Child Development

CHILD DEVELOPMENT (ISSN 0009-3920), one of three publications of the Society for Research in Child Development, Inc., is published bimonthly by Wiley Subscription Services, Inc., a Wiley Company, 111 River St., Hoboken, NJ 07030-5774. Periodical Postage Paid at Hoboken, NJ and additional offices.

Postmaster: Send all address changes to *CHILD DEVELOPMENT*, Journal Customer Services, John Wiley & Sons Inc., 350 Main Street, Malden, MA 02148-5020.

Information for Subscribers: *Child Development* is published in six issues per year. Institutional subscription prices for 2010 are: Print & Online: US$670 (US), US$938 (Rest of World), €608 (Europe), £479 (UK). Prices are exclusive of tax. Asia- Pacific GST, Canadian GST and European VAT will be applied at the appropriate rates. For more information on current tax rates, please go to www3.interscience.wiley.com/aboutus/journal_ordering_and_payment.html#Tax. The price includes online access to the current and all online back files to January 1st 1997, where available. For other pricing options, including access information and terms and conditions, please visit www.interscience.wiley.com/ journal-info.

Delivery Terms and Legal Title: Prices include delivery of print journals to the recipient's address. Delivery terms are Delivered Duty Unpaid (DDU); the recipient is responsible for paying any import duty or taxes. Legal title passes to the customer on despatch by our distributors.

For more information about Wiley-Blackwell journals, including online access information, terms and conditions, and other pricing options, please visit www.interscience.wiley.com or contact our customer service department, tel: (800) 835-6770 or +1 (781) 388-8598 (Americas); +44 (0) 1865 778315 (Europe, Middle East, and Africa); or +65 6511 8000 (Asia Pacific). Subscription in 2010 includes three issues of *Monographs of the Society for Research in Child Development* and three issues of *Child Development Perspectives*. Single issues from current and recent volumes are available at the current single issue price from csjournals@wiley.com. Earlier issues may be obtained from Periodicals Service Company, 11 Main Street, Germantown, NY 12526, USA. Tel: +1 518 537 4700, Fax: +1 518 537 5899, Email: psc@periodicals.com. Volumes 37 to date are available in microfilm from ProQuest Information and Learning, Serials Customer Service Department, 300 North Zeeb Road, Ann Arbor, MI 48106; telephone: (800) 521-0600 x2873.

Electronic Access: The *Child Development* website can be found at www.srcd.org. Abstract information for this journal is electronically available at www.blackwellpublishing.com/cdev. This journal is available online at Wiley InterScience. Visit www3.interscience.wiley.com to search the articles and register for table of contents e-mail alerts.

Access to this journal is available free online within institutions in the developing world through the HINARI initiative with the WHO. For information, visit www.healthinternetwork.org

Journal Customer Services: For ordering information, claims and any enquiry concerning your journal subscription, please go to interscience.wiley.com/support or contact your nearest office:

Americas: Email: cs-journals@wiley.com; Tel: +1 781 388 8598 or 1 800 835 6770 (Toll free in the USA & Canada).

Child Development, January/February 2010, Volume 81, Number 1, Pages 1–5

In This Issue

Crossing the Placenta

We used to think that fetuses were protected from external influences by the placenta, but we now know that characteristics of mothers' psychological state affect development of both the fetus and, after birth, the baby. Three studies in this issue address developments in this area.

Babies' development before they are born predicts their level of maturity in the first 2 weeks of life. In a longitudinal study, **DiPietro et al.** (p. 115) looked at about 100 healthy women with normal pregnancies when their fetuses were 24–38 weeks old. They measured fetal heart rate and how much the fetus moved to determine how this related to the maturity of the babies soon after birth. They found that more active fetuses had better motor development as newborns, and fetuses with more variation in their heart rate had more mature nervous systems. Additionally, they found that pregnant women who felt stressed by their pregnancies also had infants with more mature nervous systems than those who felt less stressed. The study broadens our understanding of how early development carries over to later development.

Davis and Sandman (p. 131), in a longitudinal study looking at 125 women and their babies, considered how prenatal exposure to maternal cortisol (a hormone produced in response to stress) during pregnancy affects infants' mental development. Infants who were exposed to high levels of cortisol early in pregnancy and whose moms were anxious about pregnancy performed poorly on measures of mental development at age 1. But infants who were exposed to high levels of cortisol late in pregnancy had enhanced mental abilities. In terms of the influence of mothers' cortisol on developing nervous systems, the study suggests that the timing of exposure matters and that fetuses are most vulnerable to the negative effects of stress in early pregnancy. The study can inform efforts to promote infant and child health.

Children whose mothers suffer from depression are more likely than others to develop behavioral and emotional problems. In a longitudinal study, **Hay, Pawlby, Waters, Perra, and Sharp** (p. 149) considered the role of mothers' depression during pregnancy by looking at more than 100 British youth from disadvantaged areas. Mothers who became depressed when pregnant were four times as likely to have children who were violent at 16—this was true for both boys and girls. Furthermore, women who were aggressive and disruptive in their own teen years were more likely to become depressed in pregnancy, so that the moms' history predicted their own children's violence. The findings encourage providing support for moms with a history of conduct problems who become depressed during pregnancy.

Autism: Exploring Cause and Effect

Research has shown that moms of children who develop autism have more problems during pregnancy and that their children have more problems during and immediately after birth. Do these early problems increase a child's risk of developing autism through an environmental mechanism, or are the pregnancy and birth problems themselves a consequence of the child's preexisting genetic risk for autism? In a longitudinal study, **Ronald, Happé, Dworzynski, Bolton, and Plomin** (p. 166) looked at more than 13,000 18-month-old identical and nonidentical twins born in England and Wales to see if the twin with more postbirth problems developed more autistic features by age 8 than the cotwin with fewer problems. The conclusion: a weak trend toward twins with more postbirth difficulties having more autistic features in middle childhood. Further research is needed to confirm and expand upon these findings, which have implications for treatment during pregnancy.

Early Risks and Later Outcomes

Some 4.2 million infants, toddlers, and preschoolers lived in poverty in the United States in 2007. We know that their childhoods are more difficult than those of affluent children, but what does low income in childhood mean for successes and failures later in life? **Duncan, Ziol-Guest, and Kalil**

(p. 306) used nationally representative data of more than 1,000 people born between 1968 and 1975 (the Panel Study of Income Dynamics, the longest running longitudinal study of household income in the United States) to find strong links between poverty before age 5 and lower earnings and fewer work hours 30 years later. In concluding that the age at which children live in poverty matters, the study has implications for policy.

Children who experience many early risk factors—living in poverty, being born to a teen mom, moving frequently—are more likely to have problems doing well in school and adjusting socially. In a longitudinal study of more than 100 low-income mostly African American children from infancy to age 21, **Pungello et al.** (p. 410) looked at early risk and early intervention together. They found that children who experienced more early risk were less likely to graduate from high school and get a job, and more likely to become parents as teens, whereas children who took part in an early intervention preschool program from infancy to kindergarten were more likely to attend college or get a good job. In suggesting that the intervention buffered against the harmful effects on education of living in a less than optimal home environment, the findings can help policy makers decide how to allocate limited resources.

Watching TV

American children watch a lot of TV—3.6 hours a day by the time they are 3—and there has long been concern about how TV affects children's development. In a reanalysis using data from the National Longitudinal Survey of Youth, **Foster and Watkins** (p. 368) reexamined the claim made by prior studies that TV watching in the toddler years causes attention deficit disorder (ADD) at age 7. They find no meaningful tie between TV watching and attention problems. Prior research claiming the existence of a TV–ADD link, the authors suggest, omitted key confounding variables such as poverty. This study broadens our understanding of the effects of TV on children, and also highlights the value of reanalyzing past research.

Maternal Smoking During Pregnancy—and Its Effect on Children

Mothers who smoke while pregnant tend to give birth to smaller, less healthy babies, while mothers who quit smoking are more likely to have babies with normal birth weight. This tells us that exposure to tobacco smoke harms fetal development, but less is known about the physiological processes that cause this to happen. **Price, Grosser, Plomin, and Jaffee** (p. 101) looked at the DNA of almost 500 nonidentical twins born to moms in England and Wales who smoked during pregnancy—specifically, the gene that codes for a protein that forms part of the body's defenses against the toxic chemicals found in tobacco smoke. Differences in this gene were associated with differences in birth weight. In twin pairs where one child had an inactive form of the gene and the other did not, the twin with the inactive gene tended to be born several ounces heavier. Identifying this gene provides a keyhole for future experiments on the biology of fetal development when there is exposure to smoke.

Children of mothers who smoke during pregnancy are also at risk of doing poorly academically. In a study that is based on information from more than 650,000 Swedish children and that used a quasi-experimental approach, **D'Onofrio et al.** (p. 80) suggest that it's the risk factors that accompany mothers' smoking, including shared genetic factors, that lead to poor academic achievement (measured by school grades and math proficiency at age 15), not the smoking itself. In challenging prior findings, the study has implications for public health interventions.

Caring for Children in Institutions

Research has shown that institutional care may hinder both emotional and intellectual development in young children. Based on data from the Bucharest Early Intervention Project, the first randomized controlled trial of foster care as an alternative to institutional care, **Smyke, Zeanah, Fox, Nelson, and Guthrie** (p. 212) examined whether a family-based intervention could improve the quality of attachments between Romanian 3-year-olds and their caregivers. They studied children who had been in institutions, usually from birth; children institutionalized at birth and later placed in foster care; and children raised by their families at home. Young institutionalized children who were placed in foster care before 24 months were much more likely to develop secure attachments to their caregivers than those placed after 24 months. Children cared for in institutions were more likely to have unusual and abnormal attachments to their caregivers. The study has implications for abandoned and abused or neglected children around the world who receive nonparental care, as well as for their ability to recover from their early experiences.

How does the deprivation and neglect that institutionalized children often experience affect their brains' development? **Pollak et al.** (p. 224) looked at groups of 8- and 9-year-olds, some of whom were adopted into U.S. homes from institutions in Asia, Latin America, Russia, Eastern Europe, and Africa. These children were compared to a group of American children raised in their birth families. Children who lived much of their preadoptive lives in institutions performed worse than those raised in families on tests measuring visual memory and attention, learning visual information, and impulse control. Yet these children performed at developmentally appropriate levels on similar tests involving attention, memory, and learning sounds, such as sentences, words, and phonemes. Both groups of children also performed similarly on tests of planning abilities. The take-home message: The amount of time young people spend in deprived settings may have different effects on the development of brain systems that underlie how they learn different types of information, such as sights versus sounds.

Studies have suggested that institutional care jeopardizes children's optimal development and that well-functioning child-care institutions may offer children a better environment than their own dysfunctional families. For the growing number of children who are becoming infected with HIV, questions about where they live and who cares for them are crucial. **Dobrova-Krol, van IJzendoorn, Bakermans-Kranenburg, and Juffer** (p. 237) examined the effects of perinatal HIV infection on the development of more than 60 Ukrainian 4-year-olds; some lived with their biological families and some lived in child-care institutions from shortly after birth. The quality of the child–caregiver relationship had a bigger impact on children's physical growth and cognitive performance than that of the HIV infection or the quality of the physical environment, they find. In addition, for both children with and without HIV who lived in institutions, family care, even when it was compromised, was better for children than institutional care. The study has implications for intervention efforts among children with HIV.

Effects of Early Events on Vulnerable Children

Children who are abused and neglected grow up with a lot of stress. Cortisol, termed the "stress hormone," helps the body regulate stress. But when stress is chronic and overloads the system, cortisol can soar to very high levels or plummet to lows, which in turn can harm development and health. **Cicchetti, Rogosch, Howe, and Toth** (p. 252) studied more than 500 low-income children ages 7–13, about half of whom had been neglected and/or abused, to find out whether abuse early in life and feelings of depression affected their levels of cortisol. The study's findings: Children abused in the first 5 years had more depression than maltreated children without early abuse and children who were not maltreated. In addition, only children who were abused in the first 5 years and were depressed had an atypical flattening of cortisol production during the day. The authors suggest that early abuse may be more damaging to developing emotion and stress symptoms because it happens as the brain is rapidly developing. Moreover, because it's harder for very young children to discern the clues predicting an abusive attack, they may be chronically stressed and overly vigilant, even when they are not being abused.

Early events in our lives influence how both our brains and our behavior develop. **Fox, Levitt, and Nelson** (p. 28), in a review of past research, explore how the structure of early experience weaves its way into the structure of the developing brain. First, they describe the genetic framework that lays the foundation for brain development; then, they turn to the many ways experience interacts with and modifies the structures and functions of the developing brain. Their conclusions: Although early experience is key to maintaining and elaborating our early wiring diagram, later experience also plays an important role; this later experience is critical to establishing a solid footing for development beyond the early years. The analysis has implications for policy and practice for those who work with vulnerable children.

Thought Processes and Processing Thoughts

Executive functioning is a set of advanced cognitive functions—including impulse control, working memory, and mental flexibility—that help us plan and monitor what we do to reach goals. Although executive functioning develops speedily between ages 1 and 6, children vary widely in their skills in this area. In a longitudinal look at 80 pairs of middle-income Canadian moms and their year-old babies, **Bernier, Carlson, and Whipple** (p. 326) asked why. It turns out that the ways moms act when they are playing and solving puzzles with their babies can explain some of the differences. Children of moms who answered their children's requests for help quickly and accurately; talked about their children's preferences, thoughts, and memories during play; and used successful strategies to help solve difficult problems performed better at a year and a half and 2 years on tasks that call for executive skills. The study sheds light on the role parents play in helping children develop skills deemed important for later school success and social competence.

In everyday life, people often reflect on how a past event might have turned out differently—a process called counterfactual reasoning. Some studies suggest that even 3-year-olds can reason counterfactually. However, in studies assessing feelings of regret, children show no sign of counterfactual reasoning until age 6 or older. To explore why this is so, **Rafetseder, Cristi-Vargas, and Perner** (p. 376), in a series of experiments, studied 3- to 6-year-old Austrian children as well as adults, asking them to answer counterfactual questions. Some of the questions could not be answered correctly by basic conditional reasoning ("if . . . then"), but required the respondents to think of what had actually happened. The study finds that counterfactual problems become quite difficult when basic conditional reasoning leads to a different answer than counterfactual reasoning does. So the early use of basic conditional reasoning explains why, in some studies, little sign of counterfactual reasoning emerges before age 6.

Biology Versus Psychology

Some research suggests that young children don't know a lot about biology and so they say that biological occurrences are caused by psychological factors—for example, a sibling is shaking because of fear, not a fever. **Erickson, Keil, and Lockhart** (p. 390) used implicit measures to examine whether children can distinguish biological from psychological phenomena, and how they reason differently about the processes in these two distinct categories. They conclude: Five-year-olds correctly cluster biological processes and separate them from psychological ones. Also, 5-year-olds understand that biological and psychological processes operate according to fundamentally different causal mechanisms. And they have intuitions about the broad nature of these different mechanisms—even though they may not understand the specifics behind them. This study expands our understanding of how and when children reason about biological happenings as separate from psychological ones.

Studies of Stress

Children who react highly to stress are more vulnerable to adversity and have more behavior and health problems than their peers. But a growing body of research tells us that this picture is incomplete. **Obradović, Bush, Stamperdahl, Adler, and Boyce** (p. 270) took a longitudinal look at more than 300 kindergarteners, as well as their teachers and families. Children who had significant biological reactions to laboratory challenges that mimicked daily stressors were more susceptible not only to negative environments but also to positive environments. Children who were highly reactive were more likely to have developmental problems when growing up in adverse, stressful family settings. But contrary to expectation, such children were also more likely than their less reactive peers to thrive in caring, low-stress families because of their sensitivities to the supportive and nurturing qualities of such environments. The study tells us that when children are highly susceptible to stress, it's not always bad news, but rather should be considered in terms of the type of environment they live in.

In another study on the effects of early experience on children's reactions to stress, **O'Neal et al.** (p. 290) sought to understand the relation between children's response to stress (as measured by cortisol) and aggressive behavior in almost 100 preschoolers who were at risk of antisocial behavior (their older siblings had been in trouble with the law). The study finds that in families with lower levels of parental warmth, changes in the children's response to stress that came about as a result of a preventive intervention program were associated with lower rates of aggressive behavior 16 months later. This is one of the first experimental studies with young children to establish a tie between the neurobiological stress regulation system and later aggression. By underscoring the malleability of the neurobiological system and links to behavior, the study has implications for those who work with children living in stressful circumstances.

Because the survival rate of babies born at extremely low birth weight (less than 1,000 g or 2.2 pounds) has improved markedly over the last few decades due to advances in neonatal care, it's important to track how these babies fare. In a longitudinal study, **Schmidt, Miskovic, Boyle, and Saigal** (p. 183) looked at the differences between

Canadian children born at extremely low birth weight and those born at normal birth weight in terms of anxiety, depression, and social withdrawal in middle childhood, adolescence, and young adulthood; they also considered brain-based measures of vulnerability to stress. Adults who were born at extremely low birth weight had more behavior problems from adolescence to young adulthood and their brains were more vulnerable to stress. The findings shed new light on the development of those born at extremely low birth weight, especially in terms of the ties between brain and behavior.

Refining the Nature–Nurture Debate

Children's behavior is shaped by genes and environment. Studies suggest that aggressive and antisocial behavior is influenced by moderate genetic effects, and environmental factors moderate or mediate the genetic influences on problem behaviors. Expanding work on how inherited characteristics make some more susceptible to the effects of certain environments, **Leve et al.** (p. 340) looked at infants' reactions to frustration. In their study, part of ongoing longitudinal research, the scientists observed almost 350 nine-month-olds and their adoptive parents during a frustrating task; they also interviewed birth parents. Perhaps not surprisingly, children were more likely to engage in problem behaviors on the task when they had adoptive mothers who were anxious or depressed *and* biological moms with a history of problems with substance abuse, delinquency, or other issues. But encouragingly, the adoptive children whose biological moms had problems and whose adoptive moms were *not* anxious or depressed did not act out on the frustrating task. The findings support the idea that healthy family environments can offset a child's genetic risk for difficulties, even during the 1st year of life.

Individual differences in human traits commonly flow from parent to child, prompting the question: Do children share the traits of their parents because they are raised by their parents or because they share common genes? **Meaney** (p. 41) reviewed research to examine the biological context in which genetic and environmental signals operate. He suggests that the nature–nurture debate may appear sensible, but it's really a false debate because when we understand how genes actually work within the cells of our body, it becomes clear that genetic forces simply cannot operate independently of environmental forces. The bottom line: Genetic and environmental influences—nature and nurture—work collaboratively, not as separate and opposing forces, to shape children's development. The analysis has implications for prevention and intervention programs for children and families.

Reversing Intellectual Disability in PKU Children

Phenylketonuria (PKU) is an inborn metabolic error caused by a genetic mutation that results in higher levels of phenylalanine, which can cause serious brain damage. Newborn screening for PKU, begun in the 1960s, combined with a special diet has been found to prevent intellectual disability in children with PKU. It has been thought that when children with PKU are not treated or are treated late, they suffer severe, irreversible mental retardation that cannot be reversed through diet. **Grosse** (p. 200) reviewed studies from Europe and North America and finds that following a restricted diet can boost cognitive ability in those with late-diagnosed PKU. This conclusion should encourage parents of children who missed being detected through newborn screening. That said, the study also reaffirms that early diagnosis and intensive treatment are the only ways to minimize neurological damage caused by PKU, so universal screening and prompt treatment remain urgent public health issues.

A Unified Theory of Development: A Dialectic Integration of Nature and Nurture

Arnold Sameroff
University of Michigan

The understanding of nature and nurture within developmental science has evolved with alternating ascendance of one or the other as primary explanations for individual differences in life course trajectories of success or failure. A dialectical perspective emphasizing the interconnectedness of individual and context is suggested to interpret the evolution of developmental science in similar terms to those necessary to explain the development of individual children. A unified theory of development is proposed to integrate personal change, context, regulation, and representational models of development.

The attention of philosophers and then scientists to human development has always begun with a concern that children should grow up to be good citizens who would contribute to society through diligent labor, moral family life, civil obedience, and, more recently, to be happy while making these contributions. The motivation for these concerns was that there were many adults who were not. Although attention was paid to the socialization and education of children, it was ultimately in the service of improving adult performance. The societal concern has always had a life-span perspective. Without healthy, productive adults no culture could continue to be successful. This concern continues to be a major motivator for society to support child development research. Although the intellectual interests of contemporary developmental researchers range widely in cognitive and social–emotional domains, the political justification for supporting such studies is that they will lead to the understanding and ultimate prevention of behavioral problems that are costly to society.

With these motivations and supports there have been major advances in our understanding of the intellectual, emotional, and social behavior of children, adolescents, and adults. Moreover these understandings have increasingly involved multilevel processes cutting across disciplinary boundaries in the social and natural sciences. This progress has forced conceptual reorientations as earlier unidirectional views that biological or social circumstance controlled individual behavior are becoming multidirectional perspectives where individual behavior reciprocally changes both biological and social circumstance.

The models we use to understand how individuals change over time have increased in complexity from linear to interactive to transactive to multilevel dynamic systems. Was this progression in complexity an expression of empirical advances in our developmental research or is it related to more general progressions in the history of science as a whole? Several years ago during a discussion of a need for a critical social history of developmental psychology by a number of distinguished scientists (Bronfenbrenner, Kessel, Kessen, & White, 1986), Sheldon White argued that it is necessary to engage and deconstruct the history of the field in parallel with efforts to understand the child. He continued by pointing out that the study of development needs a self-concept, just as each child requires ''the building of some kind of self-referential, self-regulating, self-knowing set of structures.''

If there is a more sophisticated understanding of the development of humans, is there a more sophisticated understanding of the development of our science? The models we use to understand the history of our field from child psychology to developmental science should increase in complexity. Understanding developmental science requires developmental science. And as in the study of any

historical process there should be hope that understanding the past will help us predict the future.

The premise of the general systems theories that arose in the 1930s was that there were general principles of organization in every scientific domain that were at a level of abstraction somewhere between mathematical formulations and the specific processes being studied (Boulding, 1956). This has become apparent in every discipline from physics to political science, as each has moved to models of dynamic regulation, where parts cannot be separated from wholes and useful predictions can only be made based on local interactions of multiple systems. The hope of the founders of general systems theory (cf. von Bertalanffy, 1968) was that scientists would use a top-down strategy to interpret empirical data from a complexity perspective (Sameroff, 1983). This aspiration was not realized because each science has tried to be as theoretically simplistic as possible, resisting the demise of deterministic models until overwhelmed by the complexity of empirical data. The science of psychology has been no exception.

Developmental research aspired to the dicta of Ockham's razor in the hope of finding simple basic elements and processes that would explain the emergence of life's complexity. Up through the 1960s and into the 1970s statistically significant *t* tests and analyses of variance gave an illusion that science was advancing, but when regression models became dominant and the metric changed to size of effects (Cohen, 1988), it became clear that the field was not doing well at explaining how children were growing up. Contemporary developmentalists are quite competent at short-term predictions of similar cognitive or emotional constructs but much worse at the prediction of long-term successful life adaptations starting from initial conditions. Increasingly, sophisticated statistical models have been sought to separate the behavioral signal of interest from the noise of real life. This effort has led to some frustration in the decreasing amounts of variance that can be attributed to any single factor when everything imaginable is controlled and obscured the possibility that the unexplained variance, the noise, might contain the signals of many other dimensions of the individual or context that are necessary for meaningful long-term predictive models.

Applicability may not be the most salient criteria for getting research accepted for publication, but it is highly salient for suggesting ways to change developmental outcomes. The science paid for by the public is increasingly being asked to meet a translational rather than a statistical criterion with the application of research to policy an important consideration (Huston, 2008). The primary question remains as to how we can improve the fate of individuals growing up in our society. To answer that question requires a continuing examination of the models we need both to study and to understand development. In what follows I will present a contemporary summary of what such models should contain and offer a suggestion for an integrated view of development that captures much of the variance that needs explaining. No part of what I propose has not been previously suggested by creative others. Combining these elements into a unified developmental theory acknowledges the contemporary zeitgeist moving toward more dynamic conceptualizations at every level of analysis that is taking place in every other scientific discipline.

A Rough History of the Nature Versus Nurture Question

Before complexity was simplicity. For developmental explanations, simplicity was expressed in appeals to aspects of an individual's nature or nurture. The history of developmental psychology has been characterized by swings between opinions that determinants of an individual's behavior could be found either in their irreducible fundamental units or in their irreducible fundamental experiences. The growth process between babyhood and adulthood could be explained either by appeals to *intrinsic* properties of the child or to *extrinsic* properties of experience. The nature–nurture question has been a central *content* of developmental research, but it can also be considered to be a major *context* for developmental research in its appeal to deterministic thinking. As a consequence the history of the nature–nurture question can be used as an organizing construct to understand the history of our field.

Practically, the nature–nurture question comes into play when a child has a problem and the question arises, "Who is responsible?" Most parents' first response is to blame the child and most professionals' first response is to blame the parents. However, most scientists know that it is both. It is both child and parent, but it is also neurons and neighborhoods, synapses and schools, proteins and peers, and genes and governments. But that conclusion does not explain how it is both. Do nature and nurture interact deterministically so that the proportions attributable to each can be decomposed or do they transact probabilistically so that the contribution of each can only be an abstraction from the activity of dynamic systems? How this question has been answered in the course of recent history offers a window into how developmental science has evolved and a perspective on how the question will be answered in the future.

Since ancient times philosophers have weighed in with their perspectives on the relative influences of constitution and experience in determining the life course, but it is in the last few hundred years that these positions have been well articulated, most notably John Locke in the 17th century and Rousseau in the 18th. I will begin my rough historical account in the late 19th century with the beginnings of empirical psychological research in the work of Francis Galton (see Table 1). Francis Galton coined the "nature versus nurture" phrase and in his view inherited characteristics were the origins of human nature. The nurture counterpoint was most strongly stated in the work of John Watson in the 1920s who propounded a new approach he labeled *behaviorism*, extending Pavlov's conditioning processes to explain human individual differences. Learning theory came to dominate human developmental research for almost 50 years strengthened by the operant paradigms promoted in the work of the Skinnerians.

This tilt toward nurture began to shift in the 1960s under assault from three directions—ethology, behavioral genetics, and the cognitive revolution. Where S-R theorists had argued that the laws of learning were primary in explaining developmental change, ethologists were demonstrating that many complex behaviors did not seem to need any reinforcement (Lorenz, 1950) and that S-R contingencies that worked in one species did not work in another (Breland & Breland, 1961). For example, rats could learn to push a lever to avoid a shock but pigeons could not. Ethologists argued that the nature of the species put large restrictions on the effects of nurture such that certain prepared responses were impervious to experience (Seligman, 1970). Statistical advances and data from large samples of twins permitted behavioral geneticists to argue that the effects of genes and environments could be separated, and that very large proportions of behavioral differences could be explained by genetic differences (Defries & McLearn, 1973). The cognitive revolution characterized in the work of Jean Piaget placed the source of development in the mind of the child. Experience was necessary for the child to construct the world but it did not play a role in individual differences.

Table 1
Rough History of Nature–Nurture

Historical era	Empirical advance
1880–1940s—Nature	Inherited differences Instincts
1920–1950s—Nurture	Reinforcement theory Psychoanalytic theory
1960–1970s—Nature	Ethology—species differences Behavioral genetics Cognitive revolution
1980–1990s—Nurture	Poverty Social ecology Cultural deconstruction
2000–2010s—Nature	Molecular biology Neuroscience

Where the nativist shift in the 1960s was driven by advances in biological science, the nurturist shift in the 1980s was driven by three advances in the social science—the war on poverty, the concept of a social ecology, and cultural deconstruction. Where behaviorist research focused on proximal connections between reinforcements and performance, scientists in other social disciplines were arguing that economic circumstance was a major constraint on the availability of reinforcements, such that the developmental environments of the poor were deprived in contrast with those of the affluent. Similar individuals in different social classes would have quite different developmental outcomes. Bronfenbrenner (1977) in his vision of the social ecology offered a more differentiated model than provided by economics alone. He identified the distal influences of family, school, work, and culture on the availability of reinforcements to the child, providing a more comprehensive empirical model for predicting individual differences in development. The influence of postmodernist deconstruction was manifest in the emergence of a cultural psychology that went beyond cross-cultural descriptive studies. Meaning rather than behavior became dominant through demonstrations that the same child behaviors could be given different meanings in different societies leading to different developmental consequences, and conversely, different behaviors could be given the same meaning leading to the same consequences.

The new millennium coincided with another swing of the pendulum in the nativist direction, again tied to major advances in biological science. Neuroscience and molecular biology have been making major contributions to our understanding of development with new technologies for imaging the brain and manipulating the genome. But, as will be discussed below, the more recent swings between nature and nurture have been getting shorter and their intermingling has been increasing.

An examination of Table 1 emphasizes the swings between the popularity of nature and nurture as developmental explanations. At each point in time there are strong adherents of both positions waiting for some new technological advance to reinforce their point of view. Although this polarity provides motivation for empirical innovation, it has the unfortunate side effect of inhibiting theoretical innovation. Despite the alternating claims that the argument is now closed by those on the frontier of new explorations of nature or nurture, the fact remains that after each advance most of the variance in long-term developmental outcomes is still unexplained. It is the pressure of unexplained variance that continually negates claims of ascendancy and dialectically motivates continuing exploration.

I have presented a descriptive case for the cycling of explanations between nature and nurture to raise the question if there is an explanation of the repetitive pattern. It could be interpreted as simply the result of technological or theoretical advances, but it also could be a phenomenon in itself. The development of the nature–nurture debate might follow developmental principles similar to those that regulate human development and the examination of the two in parallel might illuminate both.

Nonlinear Models of Development

An appreciation of cycling requires an appreciation of a number of nonlinear processes that I will discuss under the general rubric of dialectical theory with specific attention to a developmental helix and processes of differentiation and integration. Dialectics have been directly or indirectly emphasized for studying development and especially relationships (Hinde, 1997; Riegel, 1976). An initial approach to dialectics is best captured by consideration of the Taoist diagram of the dark yin and the light yang (see Figure 1) that emphasizes that opposites are in a mutually constituting relationship. They were created together and remain bound to each other. This philosophical statement is empirically validated at the most fundamental level of physics where quarks, the current basic entities, are always in a relationship with each other. At the most fundamental level of the universe there are no ultimate units, only ultimate relationships. In the dialectical yin–yang there is a *unity of opposites* and an *interpenetration of opposites*. The unity is indicated by the mutual embrace of the yin and the yang, as seen in the figure, but yin and yang also interpenetrate each other as depicted by the small black spot of yin within the yang and small white spot of yang within the yin.

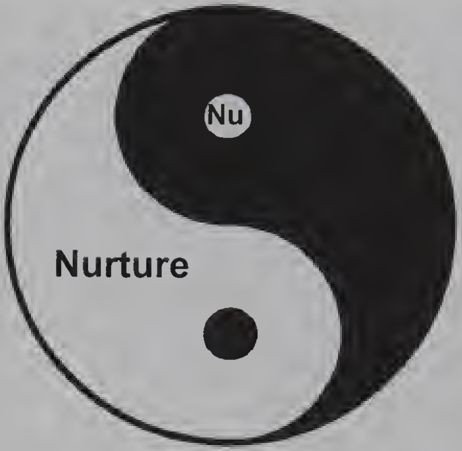

Figure 1. Unity of opposites and interpenetration of opposites in yin and yang diagram. Nu = nurture; Na = nature.

In the psychological realm these ideas have been applied frequently, beginning with the philosophical writings of Hegel and most manifest in Piaget's theory of cognitive development. There is a unity of opposites between one's cognitions and the world that is being cognized. Without the world there would be nothing to cognize, and without the cognizer there would be no cognitions. But there is also an interpenetration of opposites. One's cognition leads to one's action which becomes part of the world (the small black dot in the white area), and then the changed world becomes a part of one's cognition (the small white dot in the black area) in a continuing dialectical progression.

The dialectical perspective on nature and nurture is that they mutually constitute each other. There is a *unity of opposites* in that development will not occur without both, and there is an *interpenetration of opposites* in that one's nature changes one's nurture and conversely one's nurture changes one's nature, as captured in current transactional models. Moreover, and most salient, without the one, the other would not exist. Species and their environments evolved together in a coactive and transactional relationship. Gottlieb's (1992) construct of probablistic epigenesis centered on the joint regulation by organismic and experiential factors that produced development with neither having priority over the other. The reciprocal bootstrapping between cultural change in groups and cognitive change in individuals is well articulated by Cole (2006) in his description of human phylogeny.

Although Galton and Watson are the straw men that nurturists and nativists, respectively, rail against, both appreciated the unity of constitutions and environments. Galton (1876) recognized the influence of social class and wrote, "Nature prevails enormously over nurture when the differences of nurture do not exceed what is commonly to be found among persons of the same rank in society and in the same country." Watson (1914), in turn, recognized that individual and species differences were important, "effectiveness of habit training would be facilitated by knowledge of an animal's individual instinctive responses." The unity and interpenetration of nature and nurture will be more fully explored in the unified model of development to follow.

The Developmental Double Helix

The dynamic dialectical interplay between opposites can best be captured as an image of a helix that depicts the developmental aspects of changes over time as can be seen in Figure 2a. A simple example of a developmental progression is the daily cycle where spiraling to the right would be the movement toward day and spiraling left would be the movement toward night. Although this is a repetitive cycle, it becomes helical in that each day is different because of the experience of the previous night and each night is different because of the experience of the preceding day. A more complex example would be the development of representation in children (Werner, 1948). Initially, infants represent the world as images of here and now experiences. Preschoolers cycle over the same material but now have the capacity to depict images in drawings that may have a one-to-one correspondence to the images but are not the same as the images. In a few years they will recycle over the same contents but now with the ability to do abstract representations such as maps where the pictorial aspects may be completely eliminated in favor of words and symbols. Such developmental recycling also occurs in the social-emotional domain where relationship experiences and representations derived from early parent–child relationships are reworked as children enter into peer relationships and reworked again in the romantic relationships beginning in adolescence. Erikson (1959), although not known for his empiricism, was very articulate in describing the recycling of identity issues that are never resolved but through a balancing of opposites provide the impetus for each succeeding stage. The figure of the helix emphasizes that the same issues in a variety of domains are revisited again and again during development. The ubiquity of this helical concept is even found in Graduate Record Examination practice questions

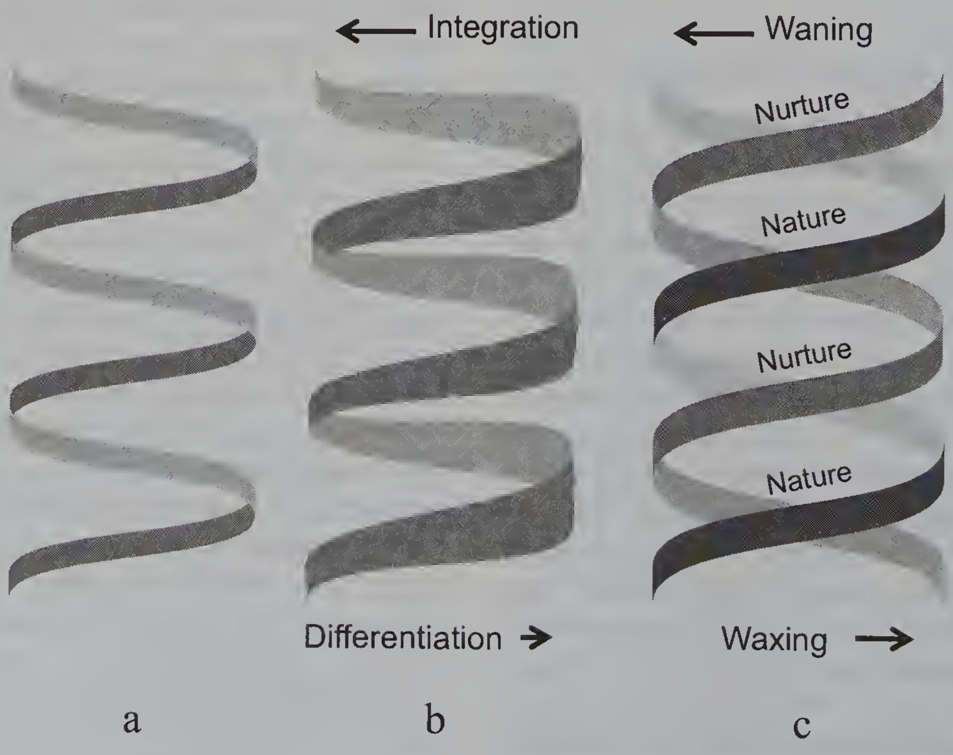

Figure 2. (a) Developmental helix. (b) Differentiation and integration of helix. (c) Developmental double helix of nature and nurture.

(Princeton Review, 2009) where a correct answer is "Science advances in a *widening* spiral in that each new conceptual scheme *embraces* the phenomena explained by its predecessors and adds to those explanations."

Differentiation and Hierarchic Integration

The developmental helix pushes us toward a more elaborate nonlinear process expressed as differentiation and hierarchic integration. As formulated in Werner's (1957) orthogenetic principle, "Wherever development occurs it proceeds from a state of relative *globality and lack of differentiation* to a state of *increasing differentiation, articulation, and hierarchic integration.*" If viewed within the helical metaphor in Figure 2b, we could consider the movement toward differentiation as going in one direction with a widening of the coil, as for example, the number of words in a child's vocabulary or the number of color concepts increases, and then the movement toward integration going in the other direction with a narrowing of the coil, as for example, the chunking of metacognition occurs, only once again to begin differentiating again as the number of metaconcepts increases.

If we consider the historical differentiation of nature, what began in Galton's laboratory as a catalogue of measurable differences in behavior was reconceptualized as really being differences in neurological electrical activity, and then as really being differences in neurotransmitter activity, and then as really being differences in genomic activity, and most recently as really being differences in epigenomic activity.

Analogously, there was also a historical differentiation of nurture where an early romantic conception of the power of mother love was reconceptualized as differences in the pattern of reinforcements provided by the parent, and then reconceptualized when it was discovered that differences in social circumstance constrained the patterns of reinforcement available to the child, and then reconceptualized when social circumstance was differentiated into the subsystems of the child's social ecology, and then reconceptualized when it was realized through social deconstruction that the effects of social ecology were constrained by the meanings that families and cultures imposed on behavior.

The progression of nature and nurture conceptions can be summarized by a double helix that captures their alternating differentiation and integration waxing and waning through time (see Figure 2c). Each new breakthrough initially goes through a stage of differentiation as a new methodology comes into play and then integration as it becomes connected to developmental phenomena. The developments in molecular biology would be a recent example on the nature side where the genome project produced the differentiated genes that now can be integrated into endophenotypes that have more proximal connections to behavior. On the nurture side, the differentiation of the social ecology into a set of subsystems of family, school, peer group, and neighborhood influences, for example, led to efforts at integrating its effect on development within comprehensive statistical models. Whether one gains ascendance over the other is a complex result of psychology (e.g., it is easier to conceptualize the parts we are made of than the wholes of which we are parts), anthropology (e.g., the preference in Western culture for individual-based rather than relationship-based explanations of behavior), sociology (e.g., whether there is a greater societal demand to mitigate the effects of biological disease or social disorder), and economics (e.g., whether investments in nature or nurture research offer the best opportunity to reduce the costs of developmental problems).

What is important in this discussion is to appreciate that there is a cycling between nature and nurture explanations of development that have a developmental course. The development of our science may be very similar to, and thus very useful for, understanding the development of human beings. The dialectics of differentiation and hierarchic integration may characterize all developmental processes.

We can come away from this discussion with one of two propositions. The first is that the cycling between nature and nurture will continue until either one or the other gets it right effectively ending the argument. Unfortunately, the problem of multifinality and equifinality undercuts this possibility (Cicchetti & Rogosch, 1996). On the nature side, whatever measure of individual differences has been discovered, two children with the same characteristics can have quite different outcomes and two children with different characteristics can have the same outcome. On the nurture side, whatever measure of the social environmental has been discovered, two children with the same experiences can have different outcomes and two children with quite different experiences can have the same outcome.

The second proposition is that nature and nurture represent a unity of opposites such that neither can ever get it right on its own. Because of their interpenetration advances in our understanding of nature illuminate nurture and changes in our understanding of nature illuminate nature. Although the literature contains many references to the fact that one cannot separate nature from nurture, there are fewer references to how their unity operates. The rest of this article will be devoted to an effort to integrate contemporary advances in our understandings of both nature and nurture into a unified theory of development.

A Unified Theory of Development

Contemporary developmental science requires at least four models for understanding human growth: a *personal change* one, a *contextual* one, a *regulation* one, and a *representational* one. The *personal change model* is necessary for understanding the progression of competencies from infancy on. It requires unpacking the changing complexity of the individual as he or she moves from the sensorimotor functioning of infancy to increasingly intricate levels of cognition; from early attachments with a few caregivers to relationships with many peers, teachers, and others in the world beyond home and school; and from the early differentiation of self and other to the multifaceted personal and cultural identities of adolescence and adulthood. The *contextual model* is necessary to delineate the multiple sources of experience that augment or constrain individual development. The growing child is increasingly involved with a variety of social settings and institutions that have direct or indirect impact as exemplified in Bronfenbrenner's (1977) view of the social ecology. The *regulation model* adds a dynamic systems perspective to the relation between person and context. During early development, human regulation moves from the primarily biological to the psychological and social. What begins as the regulation of temperature, hunger, and arousal soon turns to regulation of attention, behavior, and social interactions. The last is the *representational model* where an individual's here and now experiences in the world is given a timeless existence in thought. These representations are the cognitive structures where experience is encoded at abstracted levels that provide an interpretive structure for new experiences, as well as a sense of self and other. Combining these four models offers a comprehensive view of the multiple parts, wholes, and their connecting processes that comprise human development.

Personal Change Model

Because psychology's central focus is on individuals, developmental psychology's main concerns have been on how children change over time. How one thinks about developmental change will have a clear influence on research objectives. Three ways of conceptualizing change can be seen in Figure 3—trait, growth, and developmental. If one believes that an individual consists of a set of unchanging traits then there is no need for developmental research. If development is considered a growth process then it can have classic epigenetic explanations in that all the parts are there to start with and it is their interactions that produce the changes in the phenotype, or it can be considered experience dependent but only as nutrition for the unfolding maturation process. Viewing personal change as a stage process can have a descriptive or theoretical meaning (Kessen, 1962). Descriptive stages are paraphrases for age and consist of lists of average achievements, for example, of 1-year-olds,

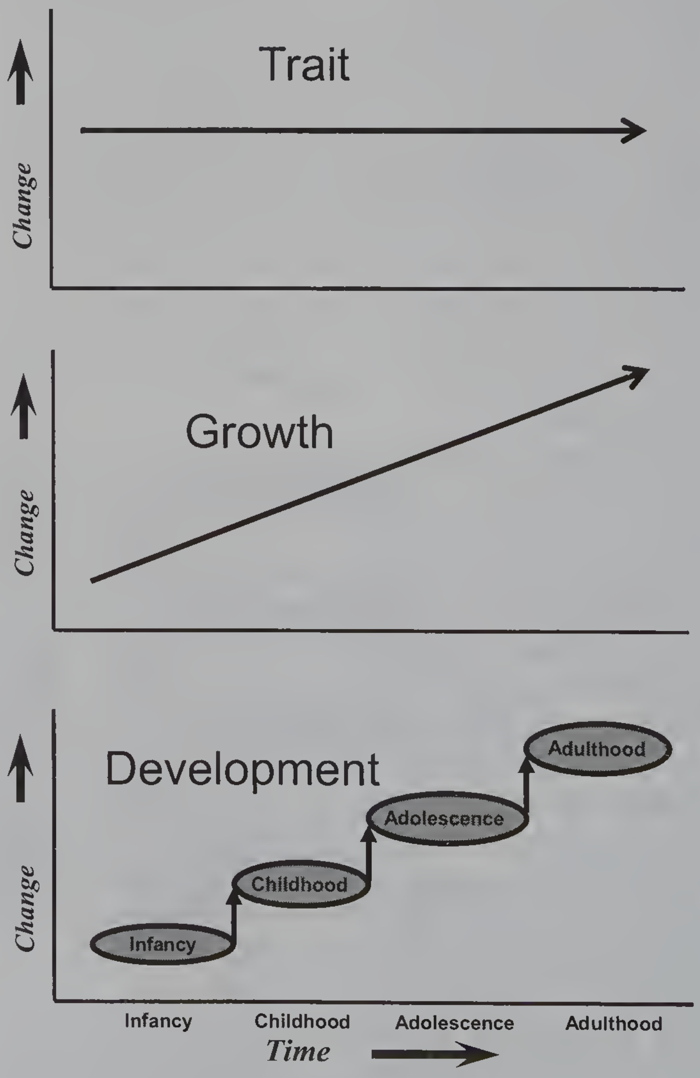

Figure 3. Personal change depicted as a trait, growth, or development.

2-year-olds, or 3-year-olds, similar to how intelligence quotient (IQ) tests are constructed. In contrast, the theoretical use of stage implies that there is a period of stability of functioning followed by a transition to a structurally different period of stability presumed to reflect more encompassing cognitive and social functioning. The classic examples of theoretical use of stages are in the writings of Freud and Piaget. Although there have been major revisions or rejections of these particular formulations, there are some generally accepted notions that within many domains individuals move from novices, to experts, to masters where they do not just do things better, they do things differently (Ericsson & Charness, 1994).

The general range of developmental changes has been extended well into adulthood and aging by the orientations of life span (Baltes, 1979) and life course theories (Elder, 1979) with their heavy emphasis on the importance of continuing alterations in the family, the workplace, and the historical epoch as individuals move into adulthood. The inability to separate individuals from context in the life-span models of adulthood provides a motivation to reconceptualize the importance of developmental context for younger individuals as well. The child or individual is not a unity and any model of the person also has to include the complex of psychological and underlying biological changes as well.

Contextual Model

Although developmental psychology is focused on individuals, it has become clear that understanding change requires an analysis of an individual's experience. Behavior, in general, and development, in particular, cannot be separated from the social context. Our understanding of experience has moved from a focus on primary caregivers to multiple other sources of socialization. There were many predecessors who felt that families, schools, neighborhoods, and culture had influences on development, but Bronfenbrenner turned these ideas into a comprehensive framework with predictions of how these settings affect the child but also how they affect each other. Although his terminology of microsystems, mesosystems, macrosystems, exosystems, and chronosystems may not be universally accepted, his principles that the family, school, and community are all intertwined in explaining any particular child's progress is now universally acknowledged (see Figure 4).

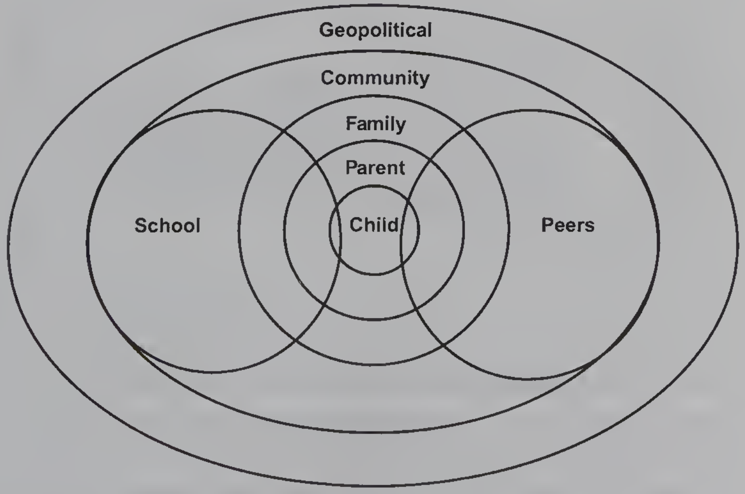

Figure 4. Social-ecological model of context.

Traditionally, social contacts were considered to expand from participation wholly in the family microsystem into later contact with the peer group and school system. Today, however, many infants are placed in out-of-home group child care in the first months of life. Each of these settings has its own system properties such that their contributions to the development of the child are only one of many institutional functions. For example, the administration of a school setting needs attention to financing, hiring, training of staff, and building maintenance before it can perform its putative function of caring for or educating children (Maxwell, 2009). Thus, a sociological analysis of such settings provides information about its ability to impact children.

Attention to the effects on children of changing settings over time must be augmented by attention to changing characteristics of individuals within a setting. Contemporary social models take a life course perspective that includes the interlinked life trajectories of not only the child but other family members (Elder, Johnson, & Crosnoe, 2003). For example, experience for the child may be quite different if the mother is in her teens with limited education, or in her 30s after completing professional training and entry into the job force.

Capturing the complex effects of multiple environmental situations has been a daunting enterprise requiring vast sample sizes to capture the unique contributions of each setting. An alternative methodology to dimensionalize the negative or positive quality of a child's experience has been the use of multiple or cumulative risk or promotive factor scores. For example, a set of data on the effects of a number of environmental variables on adolescent development was provided by a study of a large group of Philadelphia families (Furstenberg, Cook, Eccles, Elder, & Sameroff, 1999).

In the Philadelphia project 20 environmental factors were assessed and combined to approximate an ecological model containing six contextual subsystems. These were *Family Processes* that included support for autonomy, behavior control, parental involvement, and family climate; *Parent Characteristics* that included mental health, sense of efficacy, resourcefulness, and level of education; *Family Structure* that included the parents' marital status and socioeconomic indicators of household crowding and welfare status; *Family Management* composed of variables of institutional involvement, informal networks, social resources, and adjustments to economic pressure; *Peers* that included indicators of association with prosocial and antisocial peers; and *Community* that included census tract information on average income and educational level of the neighborhood, a parent report of neighborhood problems, and measures of the adolescent's school climate. In addition to the large number of ecological variables, we used a wide array of youth developmental outcomes in five domains: *Psychological Adjustment*, *Self-Competence*, *Conduct Problems*, *Extracurricular Involvement*, and *Academic Performance*.

For the environmental risk effects analyses each of the 20 variables was dichotomized with approximately one fourth of the families in the high-risk group and then the number of high risk conditions summed. When we examined the relation between the multiple risk factor score and the five adolescent outcomes, there were large declines in outcome with increasing risk and a substantial overlap in slope for each (Sameroff, 2006). Although this kind of epidemiological research does not unpack the processes by which each individual is impacted by contextual experience, it does document the multiple factors in the environment that are candidates for more specific analyses.

We also examined the effects of promotive influences in the Philadelphia study. Sameroff (1999) proposed that a better term for the positive end of the risk dimension would be *promotive* rather than protective factors. A promotive factor would have a positive effect in both high- and low-risk populations, which is far more common than a protective factor that only facilitates the development of high-risk children. We created a set of promotive factors by cutting each of our environmental variables at the top quartile, rather than the bottom, and summing them. The effects of the multiple promotive factor score mirrored the effects of the multiple risk score. Children from families with many promotive factors did substantially better than children from families with few promotive factors on each of our array of adolescent outcomes. For the youth in the Philadelphia sample, the more risk factors, the worse the outcomes, and the more promotive factors, the better the outcomes. In sum, context includes a constellation of environmental influences that have general effects on child development, fostering child development at one end and inhibiting it at the other.

Of great significance for the life course, these effects play out over time as a manifestation of the Matthew effect, "To the man who has, more will be given until he grows rich; the man who has not will lose what little he has" (Matthew 13:12). In a study of high- and low-IQ 4-year-olds we tracked their academic achievement through high school (Gutman, Sameroff, & Cole, 2003). The low-IQ group living in low contextual risk conditions consistently did better than the high-IQ group living in high risk conditions. Over time promotive or risky contextual effects either fostered or wiped out prior individual competence.

Regulation Model

The third component of the unified theory is the *regulation model* reflecting the systems orientation of modern science (Sameroff, 1983). The idea that that the child is in a dynamic rather than passive relationship with experience has become a basic tenet of contemporary developmental psychology. However, most of the rhetoric is about "self"-regulation. Whether it is Piaget's assimilation-accommodation model in cognition or Rothbart's (1981) reactivity and self-regulatory view of temperament, equilibration is primarily a characteristic native to the child. The context is necessary as a source of passive experiences that stimulate individual adaptation, but has no active role in shaping that adaptation. These views promote a belief that regulation is a property of the person. However, self-regulation mainly occurs in a social surround that is actively engaged in "other"-regulation. At the biological level the self-regulatory activity of genes is intimately connected to the other-regulatory activity of the surrounding cell cytoplasm. In Thelen's (1989) view of dynamic systems other-regulation is provided by the strange attractors of chaos theory. The self-regulation leading to an infant's neurologically based coordination of walking is constrained by the other-regulation of the child's muscle development, the strange attractor.

This issue of the developmental expansion of self-regulation to include other-regulation is captured by the *ice-cream-cone-in-a-can* model of development (Sameroff & Fiese, 2000) depicted in Figure 5. The developmental changes in the relation between individual and context are represented as an expanding cone within a cylinder. The balance between other-regulation and self-regulation shifts as the child is able to take on more and more responsibility for his or her own well-being. The infant, who at birth could not survive without the caregiving environment, eventually reaches adulthood and can become part of the other-regulation of a new infant, beginning the next generation.

It is parents who keep children warm, feed them, and cuddle them when they cry; peers who provide children with knowledge about the range and limits of their social behavior; and teachers who socialize children into group behavior as well as regulate cognition into socially constructed domains of knowledge. Although these other-regulators can be considered background to the emergence of inherent individual differences in regulatory capacities, there has been much evidence from longitudinal research among humans and cross-fostering studies in other animals that "self"-regulatory capacities are heavily influenced by the experience of regulation provided by caregivers. The capacity for self-regulation arises through the actions of others. This regulation by others provides the increasingly complex social, emotional, and cognitive experiences to which the child must self-regulate and the safety net when self-regulation fails. Children's cognition to a large extent is not derived from direct experiences with the environment but based on interpretations provided by others (Gelman, 2009). Moreover, these regulations are embedded not only in the relation between child and context but also in the additional relations between family and their cultural and economic situations (Raver, 2004). These regulatory systems range from the here-and-now experiences of parent–child interactions to governmental concern with the burden of national debt that will be passed on the next generation and to conservationists' concerns with the fate of the planet as a viable environment for future generations of humans.

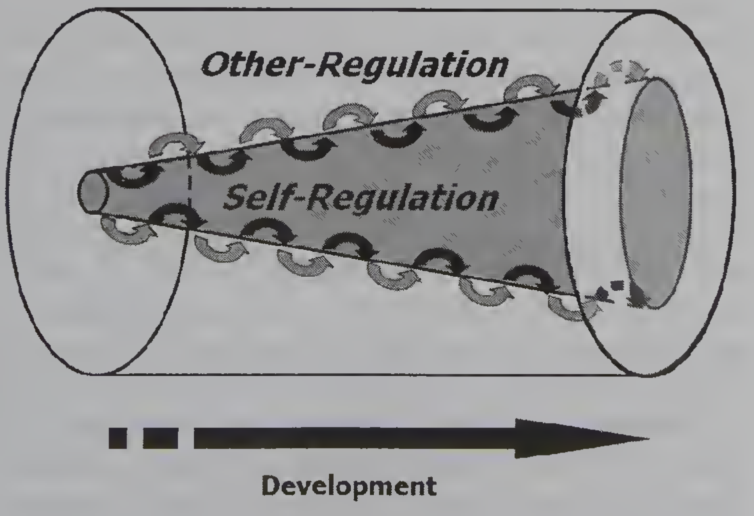

Figure 5. Transactional relations between self-regulation and other-regulation.

Early functional physiological self-regulation of sleep, crying, and attention are augmented by caregiving that provides children with regulatory experiences to help them quiet down on the one hand and become more attentive on the other. Sleep is an interesting example where biological regulation becomes psychological regulation through social regulation. As wakefulness begins to emerge as a distinct state it is expanded and contracted by interactions with caregivers who stimulate alertness and facilitate sleepiness. Although it remains an essential biological process, eventually it takes on a large degree of self-regulation as the child and then adult make active decisions about waking time and sleeping time. But this agentic decision making remains intimately connected with other-regulation in terms of the demands of school and work for specific periods of wakefulness.

Robert Emde and I with a group of colleagues (Sameroff & Emde, 1989) in an attempt to describe mental health diagnoses for infants argued for a position that infant diagnoses could not be separated from relationship diagnoses. Our point was that in early development life is a "we-ness" rather than an "I-ness." The developmental and clinical question in this case is when does diagnosis become individualized, at what stage does a child have a self-regulation problem instead of an other-regulation problem? One answer is to identify the point in development when areas of self-regulation become independent of initial regulatory contexts and are carried into new relationships. Children who have imaginary playmates provide an interesting perspective on the relation between self- and other-regulation. The more preschoolers engaged in fantasy and pretense, the more sophisticated their theory of mind (Taylor & Carlson, 2009).

Generally, research into self-regulation has focused on part processes, such as emotion or attention. Such empirical isolation obscures the larger picture in which many interacting systems are playing significant roles. Without regulation provided by the social context, for example, nutrition and temperature, the young child would not survive to engage in emotional or attentional processes.

Transactional Regulation

The previous discussion of the need for a construct of other-regulation to complete an understanding of self-regulation leads now to how the relation between self and other operates developmentally and for this we turn to the transactional model (Sameroff & Chandler, 1975). Transactions are omnipresent. Everything in the universe is affecting something else or is being affected by something else. In the transactional model the development of the child is a product of the continuous dynamic interactions of the child and the experience provided by his or her social settings. What is core to the transactional model is the analytic emphasis placed on the interdependent effects of the child and environment and is depicted in the bidirectional arrows between self and other in Figure 5.

In a recent book on the topic (Sameroff, 2009), a number of researchers documented transactional processes in cognitive and social-emotional domains where agents in the family, school, and cultural contexts altered the course of children's development in both positive and negative directions. Transactional examples have been typically in the behavioral domain with an emphasis on parent–child mutual exacerbations producing problem behavior in both partners (Patterson, 1986). More recently, transactions have been recognized in teacher–student relationships where the effects of the teacher on the child in one grade will change the reaction of the teacher in the next moving the student to higher or lower levels of competence (Morrison & Connor, 2009). Multilevel transactions have also been documented where not only the parent and child are transacting with each other but both are also transacting with cultural practices (Bornstein, 2009).

Vygotsky's (1978) zone of proximal development is analogous to transactional other-regulation in cognitive development. Successful socialization and particularly good education is based on fitting experience to the developmental status of the child. As children create their understanding of the world, the world is made more complex through steps in a curriculum to move them along toward some societal goal of mature thought. Arithmetic is an excellent example where as soon as children learn to add, they are required to learn to subtract, following which they are taught to multiply and divide. Each step is a transactional regulation of the environment by the teacher to keep one step ahead of the child's mathematical regulation. Similarly, in the social realm increases in social responsibility are paced to the success of the adjustment to previous levels of responsibility (Rogoff, 2003).

In a more popular vein Gladwell (2008) describes the life course of a number of eminent individuals in sports, commerce, and technology, where equally competent children did not achieve similar greatness because of the lack of social, educational, or technological possibilities. In each case initial advantage scaffolded the child to be able to elicit and make use of a series of opportunities documenting the transactional progression that eventually led to eminence.

Representational Model

Representations are encodings of experience. They are a more or less elaborated internal summary of the external world. They include the cognitive representations where the external world is internalized, the social representations where relationships become working models, the cultural representations of different ethnicities or social classes, and the developmental theories discussed here. Representations are obviously not the same as what they represent. They have an adaptive function of bringing order to a variable world, producing a set of expectations of how things should fit together.

We have long been familiar with such representations as perceptual constancy in which objects are perceived as being a certain size even when the sensory size is manipulated. In such a summation certain aspects are selected and others ignored. In the representation of a square for example, the size, color, and texture of the square object may be ignored. Analogously, when representations are made of a social object such as a parent, certain features are included in the representation and others are ignored. Research using the adult attachment interview (Main & Goldwyn, 1984) has found that representations of parents are often idealized, where only positive aspects are included in the mental model. Although the links between the quality of representations of child–parent relationships during infancy and those during adulthood are far from direct, early working models of attachment do seem to have long-term consequences for adult development (Sroufe, Egeland, Carlson, & Collins, 2005).

Similarly, parents create representations of their children that emphasize certain aspects, deemphasize others, and have stability over time independent of the child's actual characteristics. We had parents rate their infants' temperament during the 1st year of life following a structured interaction sequence (Seifer, Sameroff, Barrett, & Krafchuk, 1994). We also had them rate the temperament of six unfamiliar infants engaged in the same interaction sequence. The average correlation in temperament ratings of the unfamiliar infants between mothers and trained observers was .84 with none below .60. The average correlation in temperament ratings between mothers and trained observers for their own children was .35 with a range down to −.40. Mothers were very good raters of other people's children but very poor raters of their own due to the personal representations that they imposed on their observations. Documenting such differences in parent representations would be of no more than intellectual interest, if there were not consequences for the later development of the child. For example, infants whose mothers perceived them as problematic criers during infancy increased their crying during toddlerhood and had higher problem behavior scores when they were preschoolers (McKenzie & McDonough, 2009).

Individual well-being is also a result of meaningful cultural engagement with desirable everyday routines that have a script, goals, and values (Weisner, 2002). Meaningfulness, a key component of cultural analyses, is primarily found in coherent representations. Evidence of a positive effect of meaning systems can be found in Fiese and Winter's (2009) descriptions of how family routines provide a narrative representation for the rest of the family members that allows the whole to continue adaptive functioning despite the variability in the behavior of the parts. Evidence of a negative effect of lack of meaningfulness is in a study of native Canadian youth who showed much higher levels of suicide and other problem behavior when there were large inconsistencies in cultural continuity from one generation to another (Chandler, Lalonde, Sokol, & Hallett, 2003). The order or disorder in a family or society's representation of itself affects the adaptive functioning of its members.

Unifying the Theory of Development

Now that the four models necessary for a theory of development have been described, I can proceed to integrate them into a comprehensive view that contains most known influences on life trajectories. I will begin with a structural depiction of the components of the personal and contextual models containing all the pieces relevant to development. I will then add the regulation and change component of the personal model to capture the processes that produce the life course and then finish the unified theory with an overlay of the representational model.

Structural Formulation

The self is composed of a set of interacting psychological and biological processes. The psychological domains overlap in cognitive and emotional realms of intelligence, mental health, social competence, and identity, among others. These are depicted as the set of grey, overlapping circles comprising the psychological part of the self in Figure 6. Each of these psychological domains is subserved by and interacts with a set of interacting biological processes, including neurophysiology, neuroendocrinology, proteomics, epigenomics, and genomics that are depicted as a set of black, overlapping circles. Together the gray and black circles comprise the *biopsychological* self system. This self-regulation system interacts with the other-regulation system, depicted by the surrounding white circles, representing the many interacting settings of the social ecology, including family, school, neighborhood, community, and overarching geopolitical influences. Taken together the three sets of overlapping circles comprise the *biopsychosocial* aspects of the individual in context.

Process Formulation

The process formulation adds the personal change time dimension to the biopsychosocial model, which can be viewed as either a *growth model*, where the biopsychological aspects increase quantitatively over time but there is no change in their interrelationships as in the cone image (see Figure 5) or a *developmental model*, where the aspects have qualitative shifts in organization in which there are changing relations among the biopsychosocial aspects (see Figure 7).

Evolutionary theory has provided a fruitful analog for understanding the transitions that lead from one developmental stage to another. As opposed to the gradualist understanding of evolutionary changes originally proposed by Darwin that would look like the growth model, Eldredge and Gould (1972) argued that evolution was characterized by continuity evidenced in long periods of stasis where there were only modest changes alternating with discontinuity where there were short periods of rapid change that they labeled *punctuated equilibrium*. The implication was that there was a balance

between species and their ecosystems until it was interrupted by either large changes in the species or large changes in the environment that required a new equilibration. In terms of understanding developmental discontinuities in the individual, we would need to search for such changes in the child or the context that create pressures for a new equilibration. These forces are represented by the up and down arrows around points of inflection in Figure 7.

One of the most commonly accepted transitions has been the 5- to 7-year shift in cognition originally documented in 21 behavioral domains by White (1965) and accentuated in the work of Piaget. Thirty years later Sameroff and Haith (1996) and a group of contributors reexamined this transition but also asked if there were contextual changes during this age period. We reached the conclusion that there was a 5- to 7-year shift in the child if by 5 we meant 3 and by 7 we meant 10. This answer reflects the study of what might be called "part processes." If one asks whether 5-year-olds can attend, remember, have emotions, engage in social interactions, and even take charge of social interactions, the answer is yes. If one asks whether 5-year-olds can fully integrate their physical, cognitive, emotional, and social worlds, the answer is no. But neither can 7-year-olds. So what is the punctuation between the ages of 5 and 7? On average 5- to 7-year-olds can integrate several behaviors that permit the beginnings of formal education in most cultures in the world—increased cognitive ability, the ability to sit still, and the ability to pay attention. Some children have these capacities much earlier, but the requirements for successful participation in the school setting require all three plus a number of others. White's (1996) more recent conclusion was that, "what happens to children between 5 and 7 is not the acquisition of an absolute ability to reason; it is an ability to reason with others and to look reasonable in the context of society's demands on the growing child to be cooperative and responsible (p. 27)." In Figure 7 there are up arrows from self to other reflecting child advances, but there may be more powerful influences from other to self where society does the developmental punctuation by requiring the child to spend most of the day in school rather than at home. From this perspective the stages of infancy, childhood, adolescence, and adulthood could be

relabeled the home stage, the elementary school stage, the secondary school stage, and the work and new family stage.

Similar analyses can be applied to the punctuations that occur in the transition to adolescence or adulthood. It is the relation between shifts in the child and shifts in the context that mark new stages. Puberty is a biological achievement of the child but adolescence is a socially designated phase between childhood and adulthood (Worthman, 1993). Puberty is universal but adolescence is not, either in historical or cross-cultural perspective. In many cultures adolescence is directly tied to biological changes but in modernizing cultures it is more closely tied to age-based transitions into middle and high schools. Depending on the culture sexual participation can be encouraged at an early age before biological maturity or discouraged until individuals are well into adulthood. These pressures from changes in the child and the context are represented by the up and down arrows around the adolescent transition in Figure 7. In western societies, adolescence is generally recognized but the quality of the adolescent experience is quite variable and may be heavily dependent on stage–environment fit. Depending on the particular family or school system, desires for autonomy and intimacy can be fostered or thwarted moving the adolescent into better or worse future functioning. Negative psychological changes associated with adolescent development often result from a mismatch between the needs of developing adolescents and the opportunities afforded them by their social environments (Eccles et al., 1993).

The unified theory depicted in Figure 7 combines the personal change, contextual, and regulation model, but it would become overly complex to add the representational model to the figure, as well. Suffice it to say that representation suffuses every aspect of the model in the interacting identities, attitudes, beliefs, and attributions of the child, the family, the culture, and the organizational structure of social institutions. Moreover, the way developmental science conceptualizes the child may be only one of a number of possible cultural inventions (Kessen, 1979). The most important representation for current purposes is captured in the depiction of a unified theory of development. Like most theories the unified view does not make specific predictions but does specify what will be necessary for explaining any developmental phenomena. It is a reversal of the usual bottom-up empirical stance where the researcher maintains as narrow focus as possible unless forced to enlarge the scope by some contradictory findings. The top-down theoretical stance is that researchers need to be aware that they are examining only a part of a larger whole consisting of multiple interacting dynamic systems.

Future of Nature Versus Nurture

Current Nature Ascendance

The current ascendance of research using new biological measures of individual differences is the result of the interdisciplinary collaboration that Parke (2004) had indicated was essential to the advance of developmental research. These advances in molecular genetics, endocrinology, and neurology are being rapidly integrated into psychological research. The good news is that the new science is no longer based on the reductionist models of the past where linear progressions were proposed between biological entities such as genes or neurotransmitters and psychological function. In each domain multidirectional models are replacing unidirectional ones with a growing emphasis on gene–environment interactions, epigenome–experience transactions, and brain plasticity. These advances are relationship based, requiring increasingly complicated systems analyses to capture the multiple part–whole processes underlying developmental change. Nurture, for example, the environment of the gene, the environment of the cell, and the environment of the organism, are incorporated into advanced analyses of the contribution of context at every level of analysis. It is striking that the nonreductionist systems thinking that those who define psychology as a natural science have avoided is a now a central part of their colleague disciplines of biology and physics. Developmental science is benefiting from advances in the natural sciences at the theoretical as well as the empirical level.

Next Resurgence of Nurture

A renewed emphasis on the importance of nurture is underway. Again, it is a dialectical result of the inability of appeals to human nature to explain fully developmental pathways. There remain large amounts of unexplained variance. The nurture resurgence is implicit in the new directions for biological sciences such as epigenomics, described above, and will become explicit with a more powerful appreciation of the perspectives on human development provided by social sciences beyond psychology. The core element in each interdisciplinary effort is that successful developmental predictions from psychological measures are highly contingent on the social or biological context. Two of the major ingredients needing integration into a unified developmental science are the *opportunity structure* construct from sociology and economics and the *meaning making* construct from anthropology.

The important perspective that sociology adds to developmental science is that individuals are embedded in networks of relationships that constrain or encourage different aspects of individual behavior. Social institutions like families, schools, and the workplace are composed of roles that children come to understand and fill. In this view individual differences, the core of psychological concern, are limited by role demands in predicting developmental outcomes. Economists are interested in what keeps economies going and individual behavior is viewed through the lens of financial choices. The part of economics most relevant to behavioral development is the availability of an opportunity structure. Once again the predictive power of individual differences is constrained by the availability of such resources as educational systems, job choices, and social mobility that determines whether individuals have the option to use their prior competencies or not. Anthropology is indeed interested in cultural differences in behavior, but equally important for understanding development are differences in meaning systems, that is, how different cultures think about their practices. The same behavior can have quite different meanings and quite different behaviors can have the same meaning in different cultures. Again the predictive power of individual differences is constrained by how different cultures value and proscribe different behaviors.

Development of the Developmentalist

I began this article proposing that the study of the development of our field would illuminate our study of the development of individuals. Up until the 1960s *child psychologist* was the predominant label for researchers with children and the main focus was on identifying measures of stable intelligence and personality traits that would be predictive of adult performance. In the 1960s and 1970s we became *developmental psychologists* as organizational principles and emergents dominated the rhetoric around the cognitive revolution and attachment theory. During the 1980s and 1990s we reframed ourselves as *developmental scientists* when we gained a fuller appreciation of the contribution of biology and the social ecology to psychological growth. In the new millennium we again are changing our self description to *developmental systems theorists* as multilevel biopsychosocial dynamic systems are becoming the framework for understanding human change over time and statisticians are providing tools that are closer approximations to the complexity of our data.

With regard to what we have learned about nature and nurture, the future challenge is not to find new arguments for one or the other but to create a developmental model where advances in the study of both individual and context are expected and hoped for. I have proposed such a biopsychosocial unified theory of development that I hope will be useful for future research in human development. Over time the body changes, the brain changes, the mind changes, and the environment changes along courses that may be somewhat independent of each other and somewhat a consequence of experience with each other. It should be a very exciting enterprise to fill in the details of how biological, psychological, and social experiences foster and transform each other to explain both adaptive and maladaptive functioning across the life course.

Coming full circle to the dialectical principles of the yin–yang model, there are continuities as scientists concerned with greater differentiations within our biological and social experience continue to push our understanding of both nature and nurture. But there are increasing discontinuities with the rhetoric of the past as many more developmentalists realize that neither nature nor nurture will provide ultimate truths and neither can be an end in itself. Instead, each can explain the influences of the other because in the end neither can exist without the other. They mutually constitute each other through their unity and interpenetration of opposites. The schematic depiction of the unified theory of development provides an integrated way of looking at things, but also for things. Although we all have a strong desire for straightforward explanations of life, development is complicated and models for explaining it need to be complicated enough to usefully inform our understanding.

> Everything should be as simple as possible, but not simpler.

Introduction to the Special Section on The Effects of Early Experience on Development

Nathan A. Fox
University of Maryland

Michael Rutter
Institute of Psychiatry, Kings College London

One cardinal principle in developmental psychology is that early experience has a profound effect upon human development. Infants, once viewed as passive recipients of stimulation, are now understood to be active participants in the physical and social world that surrounds them. Learning takes place from a very early age and sets the course for trajectories of either adaptive or maladaptive behavior. A corollary to this principle is that there are certain periods during early development when experiences have a more significant effect than others. These periods, called sensitive or critical periods, are thought of as windows of opportunity during which certain types of experience have a foundational effect upon the development of skills or competencies. This special section of *Child Development* takes advantage of major advances in neuroscience, genetics, and improved developmental and statistical methods for studying the effects of early experience to provide readers with a broad range of review and empirical studies on this general topic. The special section is divided into seven parts: the first comprises two invited articles (Fox, Levitt, & Nelson, 2010; Meaney, 2010) that lay out important advances in neuroscience and molecular genetics. The second part provides five articles on fetal development and early experience. The third part contains three articles on perinatal experiences including low birth weight and long-term consequences on health and development, while the fourth part contains four articles on the effects of severe psychosocial deprivation, neglect, and abuse. The fifth part provides the reader with two articles on early experience and stress reactivity, while the sixth part presents three empirical articles examining basic mechanisms linking early experiences including poverty and adoption to behavior. Finally, Jack Shonkoff provides a commentary on the section with an eye toward thinking about the policy implications of the science.

The importance of early experience and the identification of sensitive or critical periods have a long history within developmental research. Much of the early work was on the effects of early handling and stress reactivity by developmental psychobiologists such as Seymour Levine (Levine, 1957) and Victor Denenberg (Denenberg, 1964). Their work, primarily in the rodent, illustrated the effects of early handling on later learning and reactivity. The notion of critical periods was introduced to developmental psychology by ethologists, such as Hess and Lorenz (e.g., Hess, 1964) with work on imprinting. Thinking about the effects of early experience on development has been solidified with advances in neuroscience that have described the pattern of brain development during the early months and years of life and the role that experience has in shaping development. Two areas of research have changed the way we conceptualize the effects of early experience and the influences of biology and nurture. The first is the work in neuroscience, done almost exclusively in rodents and nonhuman primates, on the effects of early experience on brain development. The second area is the revolution in our thinking about the role of experience in the action of genes and molecular genetics.

Neuroscience has provided an important foundation for our thinking about the role of early experience. Two lines of investigation are notable here. First, the descriptive work of Huttenlocher (Huttenlocher & Dabholkar, 1997) and Rakic (Granger, Tekaia, Le Sourd, Rakic, & Bourgeois,

1995) illustrated changes in synaptic density, increases in neural connections, and the subsequent pruning or decreases in synaptic number that occurred during the postnatal period and differed in timing of occurrence as a function of brain region. Sensory and perceptual regions displayed these changes early in life while these changes occurred later in areas of the brain involved in higher cognition. Neuroscientists such as Greenough (Greenough, Black, & Wallace, 1987) argued that the pattern of synaptic ''blooming'' and ''pruning'' was in part a function of experience and the quality of stimulation that the organism was exposed to during specific time periods. A second and related line of work in the area of perceptual development by Hubel and Wiesel (1970) described in specific detail how certain types of sensory/perceptual experience were necessary, at particular early periods of postnatal development, for the mature functioning of the visual cortex. The animal had to engage actively in the perceptual world to stimulate the development of neural structures that underlay typical depth perception and other perceptual abilities. Suffice it to say, these studies and others supported what developmental psychologists thought for many years—that the quality and timing of early experience was critical for typical brain and behavioral development. The article by Fox et al. (2010) in this special issue provides the reader with an overview of these issues and a foundation for understanding the effects of both timing and quality of experience on psychological development.

Since the discovery and description of DNA, the importance of genes for understanding human behavior has been a continued subject of debate. For many years, this debate was informed by twin and adoption studies and the field of behavioral genetics. Data from these studies provided estimates of heritability of specific human personality traits or cognitive processes and at the same time, attempted to model the effects of shared and nonshared experience on the developing child. This work has been useful in maintaining a voice in the debate as to whether development was more influenced by ''nature'' versus nurture. Two recent approaches, however, illustrate that framing the question about early experience in this manner may no longer be valid. The first approach is one that models the different ways in which gene and environment can interact (Rutter, 2007). Among these possibilities is the interaction between individuals with a particular genotype and experience. Individuals carrying a particular allelic structure (e.g., if they are homozygous for the short allele of the 5HTT gene) are more susceptible to certain types of experiences and when exposed to these events have trajectories of development that are different from individuals with similar genetic makeup but different experience. A classic study by Caspi et al. (2003) illustrated this gene by environment interaction within the realm of psychiatric disorders. Individuals who were homozygous for the short allele of 5HTT and who experienced heightened life stress were more likely to have a diagnosis of depression compared to individuals with the same genetic makeup but who experienced less life stress. The obvious implications are that both gene AND environment are playing critical synergistic roles in understanding developmental outcome.

A second, more recent approach is one driven by advances in molecular biology and encompasses the field of epigenetics. Research in this area, initially the result of work on the genetics of cancer, argues that experience influences the cellular machinery of the gene, changing in some instances, the expression of the gene and the genome itself. It is the essence of a gene by environment interaction. Experience modifies the gene and its actions creating changes in behavior and in some instances being transmitted down through genetic action to subsequent generations. This work has been brought to the field of developmental psychology by Michael Meaney and his colleagues (Meaney, 2001). Their research has illustrated at the behavioral and genetic levels how variations in caregiving experiences affect stress reactivity and learning in the rodent. Meaney's article in this special section (Meaney, 2010) is an attempt to provide the readers of *Child Development* with a basic introduction to the field of epigenetics and to the power and potential of this approach to studying the effects of early experience on development.

Research into the development of the central nervous system (CNS) has focused, as well, on the period between conception and birth. By the time a full-term infant is born the basic wiring of the CNS has been completed, the neurons that form the different layers of the CNS have all reached their destinations, and a good deal of the basic wiring in the brain has been achieved. Whereas much of the ontogeny of CNS during fetal development is under genetic control, these genes and their actions are affected by the fetal environment. At one time, this environment was thought to be protected by an impervious placenta, but we now know that exposure to a range of substances can have neurotoxic effects and that maternal psychological state as well affects fetal development. Although much of developmental psychology's efforts have been toward describing learning and development and the effects of experience on cognitive and social development postbirth, the quality of the fetal environment and the timing of exposure during fetal development to a wide range of substances appear to play a significant role in typical or atypical postnatal and human development. Five articles are included in the special section illustrating the importance of the fetal environment on subsequent development. DiPietro et al. (2010) provide the reader with a roadmap to how one studies typical fetal development across pregnancy and the meaning of variability in fetal responses for newborn CNS maturation. Two articles (Price, Grosser, Plomin, & Jaffee, 2010; D'Onofrio et al., 2010) provide readers with an example of the consequences of fetal exposure to maternal smoking. D'Onofrio et al. (2010) examine the long-term consequences on academic achievement for children whose mothers smoked during pregnancy, with the important finding that the supposed prenatal environmentally mediated effects are probably largely a function of a shared genetic liability. Price et al. (2010) demonstrate an important gene by environment mechanism for understanding the effects on intrauterine growth, and D'Onofrio et al. (2010) examine the long-term consequences on academic achievement for children whose mothers smoked during pregnancy, with the important finding that the supposed prenatal environmentally mediated effects are probably largely a function of a shared genetic liability. Davis and Sandman (2010), using data from an ongoing longitudinal study, found that the timing of cortisol levels during gestation were associated with differences in the babies' developmental level at 12 months. Finally, Hay, Pawlby, Waters, Perra, and Sharp (2010) examine the effects of maternal antenatal depression on children's antisocial behavior. Remarkably, maternal depression during pregnancy above other risk factors during pregnancy and after birth significantly predicted child psychiatric problems.

Basic research into brain development in the human fetus prior to term delivery has also informed thinking about the role of early experience amongst infants born early. Neonatology has developed the methods to increase the survival of very low birth weight infants who are, in most cases, also very premature. Although mortality has decreased in this population, morbidity due to prenatal or neonatal complications is a major issue for this population of children. But even among those very low birth weight infants who do not undergo significant medical complications, the nonfetal environment into which they are born and the stimulation of the neonatal intensive care unit are clearly nonintended with regard to typical biological growth of the CNS. Two articles in this special section directly address these questions. Ronald, Happe, Dworzynski, Bolton, and Plomin (2010) provide evidence for the very weak effects of both prenatal and neonatal complications on the incidence of autistic like features in young children. Schmidt, Miskovic, Boyle, and Saigal (2010) report on the consequences, in adult life, of being born with very low birth weight in a nonmedically comprised sample. A third article by Grosse (2010) examines the consequences of late-treated phenylketonuria on cognitive development.

Much of the work on the effects of early experience and sensitive periods on later development has been with rodents or nonhuman primates. Data in human infants have been primarily in visual perceptual development (e.g., the work of Maurer, Lewis, Brent, & Levin, 1999) or auditory perceptual development and language (e.g., the work of Kuhl, Williams, Lacerda, Stevens, & Lindblom, 1992; Neville & Bavelier, 1998). Maurer's research examined perceptual development of infants born with bilateral cataracts, studying the effect of age at which the infant had surgery to remove the cataract on subsequent perceptual processes. Neville's work examined changes in brain organization and language abilities in infants born deaf. Kuhl showed how exposure to one's native language in the first months of life determines perceptual abilities to distinguish among different phonemic contrasts during later infancy and childhood. In the case of Maurer or Neville's work, use of subjects whose sensory faculties (either vision or hearing) were severely impaired allowed exploration of the effects of early experience and timing of those experiences on development. Examination of the effects of more general psychosocial deprivation and neglect in human infants has until recently been missing from the research field.

Studies of infants who have been abandoned at birth and placed into institutions where they received minimum basic care but have been deprived of typical psychosocial stimulation have filled the gap in our knowledge about the effects of these experiences on later cognitive and social development. These studies have been in the literature for some time (e.g., Tizard & Rees, 1974) but only recently has there been a systematic attempt to examine issues of timing and sensitive periods across a wide array of domains of cognitive and socioemotional behavior. A pioneering study in the United Kingdom (Rutter, O'Connor, and the ERA, 2004) tracked the cognitive and social development of a large group of children who were abandoned at birth into the institutions that existed in Romania. A series of articles from this study illustrated the effects of early severe psychosocial deprivation and neglect on children's subsequent development—as well as the importance of timing of intervention. Three articles in the current special section follow in this model: Pollak et al. (2010) present data from a large study of postinstitutionalized children adopted by families in the United States; Dobrova-Krol, van IJzendoorn, Bakermans-Kranenburg, and Juffer (2010) examine the consequences of institutionalization and HIV infection in infants in the Ukraine, and Smyke, Zeanah, Fox, Nelson, and Guthrie (2010) present evidence on the effects on social development of a foster care/family intervention within the context of the Bucharest Early Intervention Project. Of course, one does not have to study children in institutions to examine the effects of abuse and neglect on development. There is a long history of research into the consequences of physical and sexual abuse on children's development, exemplified in the current issue by a study by Cicchetti, Rogosch, Gunnar, and Toth (2010).

Two articles in this special section examine the effects of different early experiences on children's stress reactivity. Obradović, Bush, Stamperdahl, Adler, and Boyce (2010) use a model of biological sensitivity to context in which they examine whether certain contexts and early adversity are actually advantageous for some children while detrimental to others. In a similar vein, O'Neal et al. (2010) study the effects of a randomized clinical intervention trial aimed at reducing child aggression and stress reactivity. Their findings illustrate that often one particular intervention does not affect all children in the same way.

In the sixth part of this special section three articles illustrate both the mechanism and the importance of individual differences in temperament and genetics in predicting cognitive and socioemotional development. Bernier, Carlson, and Whipple (2010) nicely demonstrate how differences in maternal behavior can enhance the emergence of executive functioning in young children. This article serves as a reminder that brain areas continue to mature well into childhood and possibly adolescence, and that experiences can enhance the emergence of functions that are subsumed by these important late maturing brain regions. Leve et al. (2010) using a longitudinal design, including a prospective adoption cohort, examine both the genetic and caregiving effects predicting externalizing behaviors. Their findings illustrate both the unique and interactive effects of maternal caregiving and infant genetic makeup in predicting behavioral outcomes. The third article in this section (Duncan, Ziol-Guest, & Kalil, 2010) examines data from the Panel Study of Income Dynamics assessing the long-term effects of poverty on adult achievement, health, and behavioral outcomes. The study confirms the fact that early experience of poverty (in this case between children's prenatal to 5th year of life) has long-term consequences on a number of health and income outcomes.

The final article of this special section is a commentary by Shonkoff (2010) that lays out the relations between basic research into the effects of early experience and constructive social policy for the welfare and good of children. Shonkoff argues that the scientific evidence—as presented in the articles in this special issue—warrants innovative approaches to creating effective and novel prevention and intervention programs for children. He presents arguments for new strategies that can reduce the effects of disadvantage and early experience with "toxic" stress. His commentary demonstrates the importance of integrating established scientific evidence from brain and behavioral sciences, benefit–cost data, and the results of randomized controlled trials on intervention/prevention. It provides the link between the articles in this special section to important policy initiatives for the good of all children.

Early life events can exert a powerful influence on both the pattern of brain architecture and behavioral development. In this study a conceptual framework is provided for considering how the structure of early experience gets "under the skin." The study begins with a description of the genetic framework that lays the foundation for brain development, and then proceeds to the ways experience interacts with and modifies the structures and functions of the developing brain. Much of the attention is focused on early experience and sensitive periods, although it is made clear that later experience also plays an important role in maintaining and elaborating this early wiring diagram, which is critical to establishing a solid footing for development beyond the early years.

Our current understanding of the role of experience in influencing the course of human development arises in large part from studies of atypical patterns and disorders of development, including disorders that arise due to adverse early experience. However, whereas studies of atypical development have done an excellent job of *describing* dimensional phenotypes that underlie disrupted development, it is imperative that we integrate these descriptive concepts with biological constructs of neurodevelopment in order to understand the relevant brain architecture and neurochemical constituents that determine responses to experience that ultimately lead to typical and atypical change (see Nelson & Jeste, 2008, for recent review). In this study we seek to elucidate the myriad ways the structure of experience weaves its way into the structure of the developing brain.

Background

The foundations of brain architecture are established early in life through a continuous series of dynamic interactions between genetic influences and environmental conditions and experiences (Friederici, 2006; Grossman, 2003; Hensch, 2005; Horn, 2004; Katz & Shatz, 1996; Majdan & Shatz, 2006; Singer, 1995). There is increasing evidence that environmental factors play a crucial role in coordinating the timing and pattern of gene expression, which in turn determines initial brain architecture. Because specific experiences potentiate or inhibit neural connectivity at key developmental stages, these time points are referred to as sensitive periods (Hess, 1973; Knudsen, 2004). Each one of our perceptual, cognitive, and emotional capabilities is built upon the scaffolding provided by early life experiences. Examples can be found in both the visual and auditory systems, where the foundation

for later cognitive architecture is laid down during sensitive periods for basic neural circuitry. The capacity to perceive stereoscopic depth requires early experience with binocular vision (Crawford, Pesch, & von Noorden, 1996), which at a later point in development may have implications for perceptual and cognitive development. Likewise, the capacity to perceive a range of tones requires variation in the tonal environment, and exposure to such variation later leads to language processing and proficiency (Kuhl, 2004; Newport, Bavelier, & Neville, 2001; Oyama, 1990; Weber-Fox & Neville, 2001). Just as a square house cannot be built on a round foundation, so must later refinements in adult perceptions reflect the architectural foundation developed through early experiences. Although early experiences are reflected in behavior, behavioral measures tend to underestimate (in part because of a lack of sensitivity and specificity) the magnitude and persistence of the effects of early neuronal development (Knudsen, 2004). In order to explore the role of timing and quality of early experiences on later cognitive function, we must therefore return to the genetic framework of the developing brain.

Genetics and Environment—The "Blueprint" for Neural Development

Refinements in the neural circuits that mediate sensory, emotional, and social behaviors are driven by experience (Feldman & Knudsen, 1998). Specifically, postnatal experiences drive a protracted process of maturation at the structural and functional level, but the very ability of such developmental processes to occur successfully is dependent in large part on the prenatal establishment of the fundamental brain architecture that provides the basis for receiving, interpreting, and acting on information from the world around us (Hammock & Levitt, 2006). While the term *blueprint* has been utilized in the past to describe a fixed set of genes with inflexible interactions, the term is used here as an analogy to a rough draft, or design—the framework from which a more defined structure will evolve. The emergence of the architecture in all vertebrate species begins early, when the fundamental cardinal axes are established in the neural plate by sets of different transcription factors that specify molecular differences, particularly growth factor signaling molecules (e.g., fibroblast growth factors, wnts) antero-posteriorly, medio-laterally, and dorso-ventrally; Puelles, 2001). In humans, this occurs within the first 2 months postfertilization (Levitt, 2000, 2003). The initial focus of brain patterning was on the nature of specification of segmented regions of the nervous system, such as the brainstem and spinal cord, in which highly conserved homeobox-containing transcription factors control "downstream" gene networks that specify motor and sensory neuron types in each segment. It has become clear, however, that developmental gene networks are a highly conserved strategy for specifying the initial plan of the central nervous system. Thus, they are utilized even in the more complex, nonsegmented anterior regions of the brain that include the thalamus, hypothalamus, basal forebrain, and cerebral cortices (Sur & Rubenstein, 2005). The gene networks in large part encode transcription factors, proteins that control (through positive [enhancing] and negative [repressing] activity) the expression of genes downstream that mediate the major histogenic events that include progenitor cell proliferation, cell fate choices, cell migration, axon and dendritic growth, and synapse formation. Collectively, these highly structured events build the early plan for brain architecture. The genetic mechanisms are thought to be highly conserved because when examined, the networks are expressed in similar patterns across rodents and humans. Experimentally, however, the genetic mechanisms through which regional patterns and connections are established prenatally have been defined in animal models, primarily rodents and nonhuman primates (O'Leary, Chou, & Sahara, 2007; Rakic, 2006). In the context of understanding clinical disorders that have a prenatal origin, the challenge has been to extrapolate that information from different species in the context of the timing of human brain development, an exercise that has received considerable attention with new database tools (e.g., http://www.translatingtime.net/). The onset of histogenesis during prenatal development provides the cellular framework necessary for establishing and modifying later developing circuitry.

The cerebral cortex has garnered substantial attention in defining key developmental features across species. This is due in part to the technical advantages of studying a well-organized, layered structure, and the functional relevance of linking typical and atypical maturation of complex behaviors and neurodevelopment. The neocortex in all mammalian species comprises six layers of neurons, the architecture, connectivity, and chemistry of which are distinct depending upon their location. The neocortex is organized to receive information from the organism's surrounding environment, typically through connections with the thalamus. It does so by integrating information within and across architecturally distinct functional domains, and then relays this information to other brain centers that generate an appropriate functional response. There are two major organizing principles of the neocortex that are guided by gradients of expressed gene networks that establish an evolutionarily conserved design. First, the precursors of different functional areas emerge during the time period when neurons are produced and are displayed in the tangential domain (roughly the first and second trimesters of pregnancy in the human; see O'Leary et al., 2007; Sur & Rubenstein, 2005). Regional specification is not absolute but does involve transcriptional networks controlling the expression of axon guidance molecules that control the initial input and output wiring plan (see below). Expansion of the size of the neocortex during evolution (e.g., 1,000-fold between mouse and human) occurs mostly in this tangential domain (Rakic, 2005). Extending through the six-layered neocortex is the most fundamental of functional units, the radial column (Rakic, 2006). Each column of cells contains well-organized networks of local circuit and projection neurons, and are built in an orderly fashion in which the neurons destined to occupy deep layers are produced, or ''born'' first, followed by more superficially displaced neurons. Though there are some differences between rodents and primates, the projection neurons, which utilize the excitatory neurotransmitter glutamate, and the local circuit neurons, many of which use the inhibitory neurotransmitter gamma-amino butyric acid (GABA), arise in part from different regions of the forebrain (Wonders & Anderson, 2007). The regions of the forebrain proliferative zones from which glutamatergic and GABAergic neurons arise are specified genetically to give rise to the unique neuron types by different sets of transcription factors. For example, glutamatergic neurons arise from the dorsal pallium, the roof of the forebrain in which cells uniquely express transcription factors like Emx1 and Pax6. GABAergic neurons destined for the cerebral cortex, joining their glutamateric neuron partners, arise from the subpallium which also gives rise to the basal ganglia. This region expresses transcription factors in the Dlx and Nkx family. The genetic influence of these initial neurodevelopmental events is illustrated by experiments in which these different transcription factors are misexpressed in different regions will result in the anomalous production of projection or interneurons in the wrong location (Hebért & Fishell, 2008).

The ''inside-out'' pattern of neuron production and migration provides the basis for building essentially similar ontogenetic radial units across functional areas, with minor variations in the ratio of excitatory to inhibitory neurons in different regions. In fact, this conserved radial organization provides the framework for later developing refinement of circuits that are influenced extensively by patterns of physiological activity through experience-dependent mechanisms (see below). The tangential patterning of the neocortex into different functional domains that are prepared to receive specific thalamic input begins as soon as the first neurons are produced and is due largely to distinctive gradients of expression of transcription factors such as emx1 and 2, pax6 and lhx2, which regulate the production of signaling molecules that include the fibroblast growth factors (fgf), bone morphogenetic proteins (bmp), and wnt proteins (O'Leary et al., 2007). Experiments in genetically manipulated mice demonstrate that by eliminating or altering the expression of just one transcription factor, the functional fate of cortical regions can be changed (Cholfin & Rubenstein, 2007). For example, *emx2* controls the expression of fgf8 near the anterior end of the cerebrum. Fgf8 alone is sufficient to specify the cortical regions that will eventually receive connections that are typical of frontal and somatosensory cortices (Fukuchi-Shimgori & Grove, 2001, 2003). This type of early genetic respecification is functionally relevant. For example, Fgf17 is responsible for the initial patterning of different frontal cortex areas (Cholfin & Rubenstein, 2007). The early specification of the neocortex by genetic mechanisms is powerful because downstream from these signaling factors are axon guidance molecules that serve as the important chemical cues for getting axons to grow into their correct target region prior to beginning the extended process of synapse formation (e.g., see Alcamo et al., 2008). Gene regulatory networks also can influence the initial size of cortical areas by modulating the number of neurons that are produced. As noted above, key to the flexibility of this early architecture is the conserved nature of the radial organization. Thus, the long-distance circuit projections that help to define functional cortical areas, and even functional differences in superficial and deep projecting neurons, are altered when the disruption of early gene networks modifies guidance cues so that atypical connections are made. Though we tend to think that genetic mechanisms are immutable, it is important to stress that expression of early gene networks can be perturbed not only by catastrophic genetic mutations that disrupt important regulatory genes but also by prenatal environmental influences, such as drugs, alcohol, toxins, and inflammatory responses. These may have less profound impacts on brain patterning but nonetheless can result in long-term disruption of cellular differentiation and behavioral development (Stanwood & Levitt, 2008).

In all mammalian species, this early period of specified patterning to generate a unique architecture is followed by an extended period of synapse formation, adjustment and pruning that typically extends from the last quarter of gestation through puberty (Bourgeois, Goldman-Rakic, & Rakic, 1999; Huttenlocher & Dabholkar, 1997). There is a unique relation that emerges between pre- and postsynaptic partners as physiological activity takes over from the activity-independent histogenic events to sculpt presynaptic terminals and postsynaptic dendrites and spines. Over the past decade, investigators have identified literally thousands of genes that encode proteins related to synapse formation, plasticity, and stabilization (Akins & Biederer, 2006; Sheng & Hoogenraad, 2007; Sudhof, 2008). While synapses can form under experimental conditions in the absence of physiological activity, experience is essential for the normally occurring regulation of the molecular basis for synapse formation. In this complex process, activity controls the expression of transcription factors that direct the downstream expression of structural proteins, receptors, and signaling molecules that are needed for synapses to function properly (Flavell et al., 2006; Majdan & Shatz, 2006; Paradis et al., 2007; Sugiyama et al., 2008). Moreover, activity regulates the distribution of key proteins within the synapse, making them available for the important task of information processing during sensitive and critical periods of development (Shepherd & Huganir, 2007).

Because of dramatic differences in brain size, the developmental timing of the histogenic events across mammalian species is unique. The process begins at about 56 days postconception and extends through the first years of life in humans. The events (e.g., cell type specification, axon guidance) that provide the initial brain blueprint, influenced by early genetic patterning, are completed early and relatively rapidly, by midgestation in the primates and the end of gestation in rodents (Levitt, 2003). The formation of neural connections, the development of unique cytoarchitecture (the structural correlate of functional areas), the growth of dendritic arbors, and the peak formation of synapses is a far more time-extensive process, extending through the second and third postnatal years in humans, 180 days in the macaque monkey, and at around weaning (21 days) in rodents. Thus, through a well-defined developmental process, the basic connectivity of local and long-distance neurons is set up to take advantage of a highly flexible organization that is both activity dependent and expectant postnatally. The continued growth of the neocortex occurs up to puberty by the addition of myelin, dendritic growth, non-neuronal cells, and a complex process of resculpting synapses whose numerical density across the entire neocortex is stable but may change in their laminar distribution. The mechanisms that control this latter event are not clear but are likely to be activity dependent. Recent studies of synaptic resculpting demonstrate that highly novel gene–environment regulatory mechanisms are at play, such as the activity-dependent movement of transcription factors from pre- to postsynaptic neurons to control maturation of neurons in a noncell autonomous fashion (Sugiyama et al., 2008).

Developmental Plasticity—Adjustments to the Architectural Plan

Although our genetic code provides an important foundation for early development, it must be understood as a framework upon which many environmental factors influence future structure and function. This can best be illustrated through studies of the sensory systems, which demonstrate the crucial role of environment in the early development and maintenance of the nervous system. Such work also demonstrates the need for patterned physiologic activity during development, as well as refinement and maintenance of detailed sensory maps. For example, supporting cells in the developing rat cochlea spontaneously release adenosine-5′-triphosphate (ATP), synchronizing the output of neighboring inner hair cells, which aids in the refinement of tonotopic maps. Spontaneous ATP-dependent signaling rapidly subsides after the onset of hearing, thereby preventing this experience-independent activity from interfering with the accurate encoding of sound. The initiation of electrical activity in auditory nerves before hearing suggests that peripheral, nonsensory cells may provide the necessary early environment for the development of central auditory pathways (Tritsch, Yi, Gale, Glowatski, & Bergles, 2007). In addition, auditory perception evolves according to the tonal rearing environment, with increased sensitivity to tones outside of those continuously experienced in the environment (Hanm, Köver, Insanally, Semerdjian, & Bao, 2007).

Similarly, in the landmark studies of vision by Wiesel and Hubel (1963, 1965), it was demonstrated that kittens reared with normal visual experience resulted in each eye having sole access to alternating columns of neurons in layer IV of the striate cortex. At birth, however, both eyes synapse on *all* neurons in layer IV. In order to assure that a neuron is stimulated by experience coming from only one eye, a competitive process occurs in which activation and neighboring inhibition result in an alternating pattern of connectivity between columns of neurons in layer IV and each eye (Wiesel & Hubel, 1965). When kittens were reared with one eye closed for a period of time after birth, the occluded eye became essentially functionally blind. This blindness is due to the elimination of connections of the closed eye to layer IV and the lack of exposure to patterned activity. If occlusion extends beyond a certain time period, the typical pattern of ocular representation cannot be recovered despite the restoration of visual input to both eyes (Wiesel & Hubel, 1965). It has been hypothesized that the initial ingrowth of axons from the thalamus to ocular dominance columns in the visual cortex is governed by molecular cues (Crair, Horton, Antonini, & Stryker, 2001; Crowley & Katz, 2000). That is not to say, however, that an *atypical* or *plastic* change in visual representation is not achievable (Amedi et al., 2007; Antonini, Fagiolini, & Stryker, 1999; Flege, Munro, & MacKay, 1995; He, Ray, Dennis, & Quinlan, 2007; Miller, Keller, & Stryker, 1989). It has recently been shown, for example, that the decreased visual acuity seen in the adult rat suffering from chronic monocular deprivation is reversed if the adult rat is treated with dark exposure prior to removal of the occlusion (He et al., 2007). The increased plasticity induced by the dark environment may be due to a lack of input to the visual cortex through the functioning eye, and therefore a reduction in the strength of previously established connections. A similar restoration of visual acuity can also be induced with chronic administration of fluoxetine (Maya Vetencourt et al., 2008). Such dramatic changes in sensory system connectivity suggest that activity-dependent potentiation of these initial axons is required to maintain connections among cortical regions. In the case of the primary visual cortex, local circuit neurons have been implicated in activity-dependent plasticity through GABAergic inhibition over a wide range of neighboring axonal paths. (Fagiolini et al., 2004; Hensch & Stryker, 2004). An altered pattern of activity through one circuit can thus radically change neighboring circuits through an increase or decrease in inhibition of mediating cells. Furthermore, visual deprivation has been shown to alter the formation of dendritic spines in the visual cortex once the pathways for normal vision have begun to potentiate (Oray, Majewska, & Sur, 2004; Trachtenberg & Stryker, 2001). Following deprivation, spines show increased structural motility—possibly allowing for plasticity of local connections—and later deterioration (Kim & Bonhoeffer, 1994; Mataga, Mizuguchi, & Hensch, 2004).

The early development of visual pathways may be likened to the laying of a foundation and scaffolding for a building. If the scaffolding pattern is changed, the building may not be constructed in its original form, though a functional alternative may be reached. Thus, irreversible changes at the synaptic level do not necessarily translate into irreversible changes in a complex behavior (Feldman & Knudsen, 1998). For example, we now understand that the sensitive period for visual representation reflects, predominantly, the critical period for thalamic input to layer IV (Antonini & Stryker, 1993; Miller et al., 1989; Pascual-Leone, Amedi, Fregni, & Merabet, 2005), but that plasticity of other sensory systems may allow a blind person to demonstrate normal—and possibly enhanced—spatial awareness (Amedi et al., 2007). Plasticity in higher regions involved in spatial awareness feeds back upon lower pathways, thus compensating for an abnormal visual representation.

Advanced perceptual processes are also dependent upon the normal development of basic visual systems. For example, early visual deprivation due to congenital cataracts can lead to subtle but persistent deficits in face processing, even when the cataracts are removed in the first months of life (Le Grand, Mondloch, Maurer, & Brent, 2001). Similarly, experience with specific faces, such as same versus different species, powerfully shapes subsequent face specialization. For example, monkeys deprived of viewing faces since birth are capable of discriminating both monkey and human faces following the selective restoration of faces in the visual environment, but *what kind* of faces determines whether that same monkey will be able to subsequently discriminate human or monkey faces—thus, monkeys selectively exposed to human faces can only discriminate human faces, not monkey faces, and monkeys selectively exposed to monkey faces can only discriminate monkey faces, not human faces (Sugita, 2008).

Sensitive Periods in the Early Development of Higher Cognitive Processes

Wiesel and Hubel's (1963, 1965) experiments involving visual deprivation brought about the concept of "sensitive" and "critical" periods in early cognitive development. "Sensitive" periods are defined as a time in development during which the brain is particularly responsive to experiences in the form of patterns of activity (Daw, 1997). Further, this time point may be termed a "critical" period if the presence or absence of an experience results in irreversible change (Newport et al., 2001; Trachtenberg & Stryker, 2001). Those factors that allow a circuit underlying cognition to be plastic—or render it unchangeable—are not yet well understood. In the area of speech and language, the maturational hypothesis predicts that native language proficiency cannot be obtained when learning begins after puberty (Bruer, 2001; Werker & Tees, 2005). Studies supporting this theory have correlated the degree of accent in a second language with age at the time of acquisition of that language (Birdsong & Molis, 2001; Johnson & Newport, 1989). Adults exposed to a second language in early childhood were found to have native-like accents and pattern of tone (Gordon, 2000; Long, 1990; Oyama, 1990; Stein et al., 2006). Other researchers have also found a negative correlation between age at acquisition and grammaticality judgments (Flege, MacKay, & Meador, 1999; Komarova & Nowak, 2001). These same studies, however, have failed to show any clear discontinuity in the relation between accent and age over the period from childhood to adulthood, thus suggesting that although a sensitive period may exist, a critical period for language acquisition is unlikely (Flege et al., 1999; Komarova & Nowak, 2001; Wartenburger et al., 2003; Weber-Fox & Neville, 2001). Many of these same investigators, however, argue that the decline in language-learning facility may be confounded by educational level and that involvement in a larger bilingual community may diminish the drive to find means for communication through a learned language (Flege et al., 1999; Hoff & Naigles, 2002; Komarova & Nowak, 2001). It has further been hypothesized that enhancements in nonlanguage cognitive systems, such as memory, may actually have deleterious effects on language learning (Newport, 1990; Newport et al., 2001). If this is the case, then the neural system responsible for language may in fact remain open, though difficult to access through adult cognitive processing or with only typical effort (the extent to which considerable effort might force open the sensitive period can be found in training studies such as those focused on teaching native Japanese speakers to perceptually discriminate and correctly produce the R/L distinction (see Akahane-Yamada, Strange, Downs-Pruitt, & Masuda, 1998; Guion, Flege, Akahane-Yamada, & Downs-Pruitt, 1998; Guion, Flege, Akahane-Yamada, & Pruitt, 2000).

Several investigators have used the theory of neural networks, originally developed for vision research, to model the activity of individual neurons and/or groups of neurons in the brain during learning (Christiansen & Chater, 2001; Morton & Munakata, 2005). These neural network models are particularly useful for comparing the experience-independent and experience-based accounts of sensitive periods because the network can be kept constant with regard to features affected by maturation, motivation, and amount of exposure. Returning to the work of Wiesel and Hubel (1963, 1965), it is important to note that the loss of binocular function in the kitten did not arise simply because of the absence of input to the occluded eye. Occluding both eyes during the same time period of development was proved not to result in loss of binocular vision (Cynader & Mitchell, 1980). It is necessary for one eye to have access to layer IV of the visual cortex whereas the other eye is denied access, allowing exclusive connectivity of the unoccluded eye to striate cortex. The irreversible loss of binocular vision during development must therefore be due to a combination of environmental experience and cortical learning processes (Knudsen, 2004; Mataga et al., 2004). The fact that the existence of a sensitive period can depend upon occurrence of a particular environment suggests that in early development, portions of networks become perceptually biased, making future modifications more difficult. For example, in the literature on both speech and face perception, the perceptual window through which faces and speech is initially processed is broadly tuned, then narrows with experience. For example, Pascalis, de Haan, and Nelson (2002) demonstrated that 6- and 9-month-old infants and adults can readily discriminate two human faces, but only 6-month-old infants can discriminate two monkey faces. Similarly, 6-month-olds given 3 months of experience viewing monkey faces can readily discriminate monkey faces at 9 months of age, whereas 9-month-old infants not afforded such experience cannot (Pascalis et al., 2005).

As a rule, circuits that process lower level information mature earlier than those that process higher level information (Burkhalter, Bernardo, & Charles, 1993; Scherf, Behrmann, Humphreys, & Luna, 2007). For example, in the neural hierarchy that analyzes visual information, low-level circuits that analyze the color, shape, or motion of stimuli are fully mature long before the high-level circuits that analyze or identify biologically important stimuli, such as faces, food, or frequently used objects (Burkhalter et al., 1993; Knudsen, 2004; Scherf et al., 2007). The process by which initial learning leads to a constraint on later learning is termed *entrenchment* and is equally apparent in the development of speech (Munakata & Pfaffly, 2004; Seidenberg & Zevin, 2006). Several studies have shown, for example, that adults are often better at discriminating nonnative phonetic contrasts when they differ substantially from phonemes of their native language (Best, McRoberts, & Sithole, 1988; Frieda, Walley, Flege, & Sloane, 1999; Guion et al., 2000; Kuhl, 2004). Adults are poorer at discriminating when the phonetic contrasts are similar to phonetic contrasts of their native language. This is akin to the nature of the developing auditory system, which as previously noted is more capable of discriminating tones outside of the tonal environment of rearing. At both the level of tone and of speech phonetic discrimination, there is evidence for a fixed bias of the neural network. As previously discussed in the case of visual networks, however, neurons may be constantly modifying connectivity, allowing learning from new environments to compete against already existing tendencies. This is well demonstrated in animals altered neonatally to receive retinal projections to the auditory portions of the thalamus (von Melchner, Pallas, & Sur, 2000). Such animals reveal that auditory cortex may be modified by extrinsic activity to develop retinotopic maps similar to those seen in the visual cortex. The role of environment and inputs to the brain may therefore be seen as critical in the bias of network formation during early life.

Altered patterns of enhancement and inactivity are thought to be the basis for neural plasticity and have been suggested in humans by studies of tactile and auditory perception in the blind, where such systems may even activate the "visual" cortex (Antonini & Stryker, 1993; Ellis & Lambon, 2000; Merabet, Rizzo, Amedi, Somers, & Pascual-Leone, 2005). It is likely that changes in experience have a greater impact on an untrained "young" network compared to the same experience on an "older" trained network. This biasing feature is suggested by studies on aphasia that show that words learned earlier in life are more resistant to loss and are more easily accessed in naming tasks compared to words learned later (Greenough, Black, & Wallace, 1987).

It has been suggested that learning through experience leads to the capacity to understand specific environments and the responses needed for these environments (Anisman, Zaharia, Meaney, & Merali, 1998; Scarr & McCartney, 1983). Similarly, changes in the environment—particularly when they are dramatic and pervasive—may have the power to alter neural connectivity and cognitive processing between systems. Examples can be found in studies of sensory deprivation, such as blindfolding, as well as sensory enhancement through technology. In studies of deaf children receiving cochlear implants, it is clear that language learning improves with earlier correction (Tomblin, Barker, Spencer, Zhang, & Gantz, 2005). It remains to be determined, however, whether this effect upon learning is due to actual changes in cognitive capacity or changes in the learning environment brought about by the ability to interact with others through spoken language.

Global Development—Higher Level Functions Build on Lower Level Functions

The nature of our experiences, particularly during a time-limited period in early development, can profoundly affect the mental framework we use to understand the world around us. Sensitive periods in child development are of interest because they represent a time frame in which our capabilities can be modified and perhaps enhanced. The quality of experiences during such periods—be they adverse or enhancing—is also of importance in understanding why it may be difficult to restore normal function once development has been altered. While explanatory models for the timing of early experiences have generally been based at the genetic or neural circuit level, our direct observations of the effects of early environments are often made at the behavioral level. Through the study of sensitive periods, we are better able to understand the impact that early experience may have upon development. To cite but one example, it has recently been demonstrated that otherwise typically developing young children institutionalized at birth have intelligence quotients (IQs) in the low 70s. However, placing such children in high-quality foster care *before the age of 2 years* leads to a dramatic increase in IQ (Nelson et al., 2007). A similar trend also occurs for language (Windsor, Glaze, Koga, &

the BEIP Core Group, 2007) and the development of the EEG (Marshall, Reeb, Fox, & the BEIP Core Group, 2008), although in the case of the former, the sensitive period occurs around 16–18 months.

It is important to note recent work suggesting that the brain retains the capacity to adapt and change throughout the lifespan (Crawford et al., 1996; Jones, 2000; Keuroghlian & Knudsen, 2007). However, the foundation of brain architecture must lie in the early developmental years, and the influence of childhood environment is much more salient in such basic cognitive processes as sensory perception (Amedi et al., 2007; Antonini & Stryker, 1993; Grossman et al., 2003; Hensch, 2005; Hess, 1973; Karmarkar & Dan, 2006; Knudsen, 2004; Pascual-Leone et al., 2005). Each sensory and cognitive system reaches a unique sensitive period (Daw, 1997), and thus identical environmental conditions will result in very different cognitive and emotional experiences for a child, depending upon his or her age (Amedi et al., 2007; Jones, 2000; Trachtenberg & Stryker, 2001; Tritsch et al., 2007; for reference, see Bailey, Bruer, Symons, & Lichtman, 2001).

Behavioral analysis can demonstrate the value of early experiences in the development of the brain. It must be remembered, however, that information is processed in a series of networks, each reflecting the effects of environment at varying time points. Higher level processing may mask modifications in lower level networks (Daw, 1997; Feldman & Knudsen, 1998; Trachtenberg & Stryker, 2001). Thus, behavioral outcomes may be shaped by later experience, even though circuits at the lowest levels in a pathway remain irreversibly altered. In addition, studies of the plasticity of sensory processing reveal that similar information can be derived from alternative pathways (Akins & Biederer, 2006; Antonini & Stryker, 1993; Ellis & Lambon, 2000; von Melchner et al., 2000; Pascual-Leone et al., 2005). For example, when using sound devices to asses space, blind individuals have been shown to activate the lateral occipital cortex in the same manner as sighted individuals do through vision (Amedi et al., 2007). It has been suggested that loss sensory input—such as occurs in late blindness—may in fact lead to the unmasking and strengthening of alternative pathways stemming from multisensory integration regions of the brain (Pascual-Leone et al., 2005). These pathways may not only substitute for the original sensory inputs but may also enhance previously existing capabilities. This form of sensory enhancement can often be seen in the highly tuned auditory and tactile perception of blind.

High-level neural circuits that carry out sophisticated mental functions depend on the quality of the information that is provided to them by lower level circuits. Low-level circuits whose architecture was shaped by healthy experiences early in life provide high-level circuits with precise, high-quality information. High-quality information, combined with sophisticated experience later in life, allows the architecture of circuits involved in higher functions to take full advantage of their genetic potential. Thus, early learning lays the foundation for later learning and is essential (though not sufficient) for the development of optimized brain architecture. Stated simply, rich early experience must be followed by rich and more sophisticated experience later in life, when high-level circuits are maturing, in order for full potential to be achieved (DeBello & Knudsen, 2004; Karmarkar & Dan, 2006; Nelson, de Haan, & Thomas, 2006; Sabatini et al., 2007).

Concluding Comments

Although studies of the adverse effects of deprivation on brain development are powerful and compelling, they tell us little about the benefits of enrichment. Much of what we know about the impact of early experience on brain architecture comes from animal or human studies of deprivation. As we work to clarify further the patterns of genetic expression required for normal neural structure, we have also recognized that an optimal level of environmental input or "expectable" environment must exist in parallel. Increasing evidence suggests that this "expectable environment" of early development requires not only the variation in light necessary for vision, or the tones heard in a spoken language, but also the emotional support and familiarity of a caregiver (Nelson et al., 2007; Sánchez, Ladd, & Plotsky, 2001). It is important to emphasize that the well-documented negative impacts of deprivation on brain circuitry do not mean that *excessive* enrichment produces measurable enhancements in brain function. A small number of case reports exist in which neglected children with very little language experience in early childhood were given enriched language exposure in a protective environment (Curtiss, 1977; Itard, 1801/1932; Zingg, 1940). Longitudinal follow-up studies of these children demonstrated that after several years of language exposure, they were unable to achieve adult-level native language abilities. In animal models, rat pups deprived of maternal care were shown to have reduced hippocampal volume compared to pups with "enriched" maternal care (Bredy, Humpartzoomian, Cain, & Meaney, 2003). Placement of deprived pups into an "enriched care" environment resulted in learning and memory aptitude similar to high-care pups; however, hippocampal volume did not change, suggesting that plastic mechanisms early in life allow for alternative pathways to form typical behavior despite lasting structural deficits. Most recently, early intervention to correct a deeply impoverished early environment has been shown to greatly improve cognitive, linguistic, and emotional capabilities in humans (Ghera et al., 2009; Nelson et al., 2007; Windsor et al., 2007). Activity-dependent mechanisms of network formation, as described earlier, may be responsible for such changes when children are placed into a stimulating environment for learning and exploration. With continued research into the modification of sensitive periods, as well as the factors influencing cortical plasticity throughout life, we may remain optimistic about the possibility of recovery from early deprivation. This in turn may provide hope for children who lack the biological framework or necessary environment required for optimal neural and cognitive growth.

Finally, the possibility of cognitive and neural rehabilitation leads to theories of enrichment beyond the norm to a level of *enhanced* development. Educational and environmental enrichment of preschool children from impoverished economic settings has been shown to improve cognitive measures through early adulthood (Campbell, Pungello, Miller-Johnson, Burchinal, & Ramey, 2001; Martin, Ramey, & Ramey, 1990; see Farran, 2000, for review). Cognitive capabilities, however, may follow a pattern similar to the growth curve of the human body; that is, although it is possible to enhance the environment of a child to assume the pattern of the normal curve, it is not possible to exceed the predicted trajectory to a significant extent without causing some potential harm. This is suggested by large studies of children from varying socioeconomic status, which demonstrated an improvement in cognitive performance only in those born to a low socioeconomic class, with no significant difference between those of middle-class and high-income families (Jeffaris, Power, & Hertzman, 2002). If the possibility for enhancement exists, it is perhaps related to forms of enrichment that lie outside access to unlimited resources—that is, beyond the expectable environment. Creativity, for example, is a key component to enhanced cognitive functioning, yet we have not been able to define the neural processes or environmental attributes that can enrich this aspect of cognition, nor are there sure-fire ways of boosting creativity among the population at large. Similarly, exposure to art or music or great literature or horseback riding may not confer any evolutionary advantage (i.e., reproductive success), yet these activities may confer some advantage among certain strata of society. Thus, perhaps it would be useful to draw a distinction between *enrichment* as applied to those experiencing downward deviations from the expectable environment (such as those reared in situations of neglect or deprivation) and *enhanced enrichment* applied to those reared in typical (expectable) environments. Enrichment may lead to a restoration of typical development whereas enhanced enrichment may lead to exceeding the typical environment. Of course, a challenge here lies in accounting for individual differences, as some individuals have greater potential to benefit from art or music lessons than others. Individual heterogeneity may be under control of Gene × Gene, Gene × Environment, and Environment × Environment factors. For example, animal studies show that epigenetic mechanisms—whereby environmental factors and experiences early in life can permanently alter the genome of an individual through chemical modification—will impact long-term cognitive and social-emotional functioning (Szyf, McGowan, & Meany, 2008). The field awaits translation of this type of mechanism into human experiences. Finally, how might the field of developmental psychology benefit from advances being made in developmental neuroscience? First, given that our genome contains many fewer genes than we surmised even a decade ago (approximately 20,000), and given advances being made in the field of epigenetics, renewed attention should be paid to the origins and elaboration of complex human behaviors. Second, those working in the field of intervention should take stock in what is now known about neural plasticity; for example, it is quite possible that we could witness a revolution in new treatment approaches based on what we know about the malleability of the human brain. Finally, for the millions of children around the world who begin their lives in adverse circumstances, we should be mindful of what is known about sensitive periods and act with alacrity to improve the lives of these children before neural circuits become well established and, thus, difficult to modify. To borrow an analogy from economics, by investing early and well in our children's development, we increase the rate of return later in life and in so doing improve not only the lives of individuals but of societies as well.

Epigenetics and the Biological Definition of Gene × Environment Interactions

Michael J. Meaney
McGill University

Variations in phenotype reflect the influence of environmental conditions during development on cellular functions, including that of the genome. The recent integration of epigenetics into developmental psychobiology illustrates the processes by which environmental conditions in early life structurally alter DNA, providing a physical basis for the influence of the perinatal environmental signals on phenotype over the life of the individual. This review focuses on the enduring effects of naturally occurring variations in maternal care on gene expression and phenotype to provide an example of environmentally driven plasticity at the level of the DNA, revealing the interdependence of gene and environmental in the regulation of phenotype.

The nature–nurture debate is essentially a question of the determinants of individual differences in the expression of specific traits among members of the same species. The origin of the terms *nature* and *nurture* has been credited to Richard Mulcaster, a British teacher who imagined these influences as collaborative forces that shape child development (West & King, 1987). History has conspired to pervert Mulcaster's intent, casting genetic and environmental influences as independent agents in the field of development. The intent of this article is to examine the biological context in which genetic and environmental signals actually operate. The result of this analysis produces an impression that lies close to Mulcaster's formulation.

Any successful attempt to constructively leverage the remarkable advances of the genomic era will depend upon our ability to understand genetic influences and their interactions with the environmental context within which they operate. Hindering such efforts is the rather arcane notion that we can partition the causes of individual differences into distinct genetic *or* environmental spheres of influence. This issue is of particular importance in the area of child development where research that examines the origins of individual differences in complex traits often forms the basis for extensive intervention or prevention programs (Fisher, Gunnar, Chamberlain, & Reid, 2000; Olds et al., 1998). Our assumptions concerning the processes of child development influence the design of such programs. Thus, one of the great challenges at this time is that of integrating genomics into the design of prevention and intervention programs. In the social sciences, and particularly psychology, there has generally been an understandable bias in favor of explanations derived from the "nurture" perspective, which emphasizes the capacity for environmentally induced plasticity in brain structure and function. Nevertheless, over recent decades there has been a gradual, if at times reluctant acceptance that genomic variations contribute to individual differences in brain development and function. And thus the integration of genetics into psychology and psychiatry has become one of the more active research areas in the study of neural function. Now that we have come to accept the idea that genomic variation influences brain development and function in humans, it is time to consider what this should mean in the reformulation of intervention programs that target children and their families.

The idea that variation in the expression of neural functions would lie outside the dominion of genomic influences is biologically untenable. Like any tissue, the development of the mammalian brain and its function occurs as a result of coordinated influences that include heritable variation in genomic sequence. What remains as a major challenge for the psychological sciences is the development of a conceptual framework from which to meaningfully understand the results of studies that examine brain development and function at the level of the genotype. However, we remain mired in additive models of explanation within which phenotypic development rolls out as the cumulative by product of genetic + environmental

influences, with each discipline adding independently to the equation. Science in the postgenomic era requires a more sophisticated, biologically informed understanding of the interplay between gene and environment in defining individual differences at the level of complex traits.

The fundamental question is that of the relation between genotype and phenotype: How do variations in the genotype influence selected traits at any point over the lifespan? This question is addressed very differently in epidemiology and the social sciences than it is in the biological sciences. Indeed, the actual meaning and interpretation of the term *gene* can differ across research domains (Griffiths & Tabery, 2008). For epidemiologists or those employing epidemiological approaches, genotype–phenotype relations are defined by statistical probabilities. A gene *for* aggression is thus defined as a genomic region within which a defined variation in sequence predicts a specific phenotypic outcome, in this case one associated with aggressive thoughts or actions. Here, genotype–phenotype relations are statistical. For the biological scientist, genotype–phenotype relations are defined by the actual physical operation of a genomic region in relation to the proximal cellular events that directly mediate the behavioral variation as well as the more distal influences that regulate the relevant cellular signals. Thus, a gene *for* aggression would be defined as a genomic region from which a transcribed product actively participates in a biological pathway that *directly* mediates the expression of aggressive behaviors. The studies of Young and colleagues (Donaldson & Young, 2008; Hammock & Young, 2005) on the sequence variation in the vasopressin 1A receptor gene provide an excellent example. Among voles, subspecies differences in social behaviors are associated with a sequence variation in the vasopressin 1A receptor gene and differential expression of the vasopressin 1A receptor. Reversing the pattern of vasopressin 1A receptor expression eliminates the differences in selected, vasopressin-mediated social behaviors (see Robinson, Fernald, & Clayton, 2008, for additional examples). These studies describe a causal genotype–phenotype relation. Within the biological sciences, the mere statistical relation between a genomic variation and phenotypic outcome would not be considered as sufficient basis for the establishment of a functional link between the gene (or its product) and the relevant variation in phenotype. Such differences in perspective have led to rather lively debates between, for example, researchers in quantitative behavioral genetics and researchers examining the biological basis for individual differences in neural function (Griffiths & Stotz, 2007; Griffiths & Tabery, 2008; Moss, 2005).

The issue becomes even more complicated when considering the interaction between gene and environment, since the statistical approaches to the study of Gene × Environment interactions are complicated and not yet fully developed. Indeed, since the time of Fisher and Haldane there has been debate concerning the adequacy of analysis of variance (ANOVA) models in detecting Gene × Environment interactions (Wahlsten, 1990; see also Griffiths & Stotz, 2007; Griffiths & Tabery, 2008, for historical reviews). The primary objective of this article is to examine the Gene × Environment interaction from the biological perspective. For whatever the difficulties in statistically defining Gene × Environment interactions, research in biology reveals that the genome cannot possibly operate independent of its environmental context. The biological perspective reveals the futility of the nature–nurture debate and of additive models of genetic and environmental influences in defining phenotype. Moreover, recent studies from the field of epigenetics provide insight into biological mechanisms whereby Gene × Environment interactions can biochemically alter the genome and thus stably influence individual differences in neural function. Developmentalists studying the enduring effects of early experience on brain development and function have long anticipated such processes (Bateson et al., 2004; Gottlieb, 1997, 1998; Schneirla, 1966). This approach envisions development as an active process of adaptation that occurs as a function of the continuous dialog between the genome and its environment. With the integration of epigenetics into developmental psychobiology, we can now begin to define the physical basis for this interactive process.

Statistical Approaches to the Study of the "Instrumental" Gene

Research examining the potential influence of heritable variations in DNA sequences on brain development and function in humans has relied largely upon two approaches. The first is a classical epidemiological approach that involves association or linkage analyses that essentially use correlational approaches to describe genotype–phenotype relations. Much as epidemiological research statistically associates specific exposures with health outcomes, such studies correlate variation in nucleotide sequence at specific sites in the genome with a phenotypic outcome. This is certainly a reasonable approach in the initial phase of examining the *potential* role for a specific genomic variant (Plomin & Rutter, 1998). The advent of high-throughput technology permits genome-wide association studies that can potentially scan 1 million or more single nucleotide polymorphisms in individual subjects. While there are inherent statistical complications, such as controlling for multiple comparisons, the notion of being able to examine the relation between 10^6 sequence variants with a single trait of interest across a sufficiently large sample is incredibly seductive. Nevertheless, such studies do not inform at the level of causal mechanism. A correlation between a genomic variant and a developmental outcome is no less correlational and no more explanatory (or mechanistic) than is the correlation between, say, level of education or a dietary constituent and the same developmental outcome. The popular press often trumpets such findings (usually simply echoing the institute's own press release) as the identification of a gene *for* an outcome of interest. Studies that, for example, statistically identify a relation between a genomic polymorphism and the variation in the occurrence of conduct disorder are interpreted as successfully revealing the gene *for* conduct disorder. Such interpretations drive many scientists slightly mad, since the data are merely correlational and do not imply a cause–effect relation between the genomic variant and conduct disorder. The gene might indeed be expressed only in the liver and influence the development or activity of the relevant neural systems that regulate social behavior only through a very general metabolic pathway that fuels brain development in early life. There may be no direct effect on any neuronal population whatsoever, let alone the complex neural network that underlies the ability to regulate affect and behavior. Nevertheless, the genomic variant is indeed statistically associated with conduct disorder. The controversy surrounding the claims from association or linkage studies lie in the interpretation of the data and the implicit confusion of correlation with causation. The data are safely assumed to provide the identification of *potential* influence over the phenotype in question. However annoying the misuse of such correlational data in public or professional discourse, the findings serve as a starting point for research examining the possible functional relation between the genomic variant and the phenotype. In the case of our example, the nature of the relation between the genomic variant of interest and conduct disorder must then become a matter of more precise studies that directly examine the functional significance of that genomic variant, as well as the particular circumstances under which the genotype–phenotype relation is apparent (Plomin & Rutter, 1998).

A second statistical approach is one that has evoked greater controversy. Quantitative behavioral genetics does not examine genotype–phenotype relations at the level of specific genomic variants but rather attempts to partition the variance in the expression of a specific phenotypic traits across a population into that associated with "genetic" or "environmental" influences (Plomin, DeFries, & McClearn, 1990). Such studies actually examine so-called genetic effects without ever directly examining the genome let alone variation in the genome (Sokolowski & Wahlsten, 2001). Indeed within quantitative behavioral genetics the issue that is directly under study is that of heritability. Genetic effects are simply implied on the basis of data derived from studies of the heritability of traits. This statistical approach, based on the development of ANOVA models by Fisher and Haldane at the turn of the last century, has a long history in agriculture and animal sciences as the basis for selective breeding for specific traits (Griffiths & Tabery, 2008; Wahlsten, 2003). Such endeavors do not rely on the assumption that heritability necessarily reflects a genomic mechanism for the transmission of individual differences in the trait from parent to offspring. What is critical for selective breeding is the ability to reliably estimate the passage of traits from the parent to offspring. Traits with greater heritability are better candidates for selective breeding. The actual mechanism of inheritance is irrelevant. I think that the situation in the biological sciences is mixed. For some, heritability simply reflects familial transmission. For others, it has come to be equated with a true estimate of variation due to variation in genomic sequence. Estimates of heritability are commonly equated with "genetic" influences. It is this assumption that proves controversial.

Johannsen (1911) first introduced the terms *genotype* and *phenotype* and the relation between the two became perhaps the defining question in biology. In the study of genotype–phenotype relations, the term *phenotype* refers to all aspects of gene function and may thus be used to describe any observable characteristic of an organism, such as its morphology, biochemical or physiological properties, or behavior (Johannsen, 1911; Lewontin, 1974). The gene had actually been the subject of scientific analysis well before the early 20th century and long before the identification of DNA as the physical basis for the "genetic code." Over this period, the gene was considered as the hypothetical physical constituent of the cell, the transmission of which from parent to offspring served as the basis for Mendelian inheritance (Griffiths & Stotz, 2007; Griffiths & Tabery, 2008). The gene was defined as the "unit of heredity." And thus it was understandable that during this period estimates of heredity were assumed to reflect a genetic influence. This was true by definition. Griffiths and Tabery (2008) thus refer to this entity as the "traditional gene" —the substance of inheritance. For the early pioneers in genetics such as Morgan, and many studying patterns of inheritance to this day, the actual physical identity and operation of the gene is irrelevant (Falk, 1986). This tradition continues within the study of quantitative behavioral genetics for which the gene is simply viewed as the unit of inheritance, with apparently little concern for the actual biology that might mediate the relation of the genomic variant, cellular function and the trait of interest.

A classical research approach in quantitative behavioral genetics has employed studies of twins to infer "genetic" influences. Twin studies rely on the level of similarity in specific traits between monozygotic and dizygotic twins to derive estimates of heritability (h^2). As noted earlier, such measures were developed in animal sciences using parent–offspring regressions to study intergenerational transmission of specific traits. The intent of such studies is not to identify the causal interplay between gene and environment in defining the development and expression of a particular trait in an individual but rather to estimate the relative contribution of genetic and environmental influences in defining the variation in the trait across a population (Plomin et al., 1990). The focus on "relative contributions" of gene and environment as *independent* forces is the hallmark of quantitative behavioral genetics and assumes that such forces can act independently of one another. In following the biometric tradition of Fisher and Haldane, the variance in the expression of a phenotypic trait across a population is examined using ANOVA models that partition variance in phenotype according to genetic and environmental factors. Note that within such analyses the "genetic" influences are defined *statistically* and not biologically, and of course the same is true for the definition of so-called environmental influences. Moreover, the resulting analyses are an attempt to understand the source of variation in phenotype across a population and not as an explanation for individual patterns of development (Griffiths & Tabery, 2008).

Studies of the heritability of selected traits thus yield *statistical* and not *biological* evidence for a genetic influence. The irritation derives from the interpretation of such findings, and in particular the notion of "main effects," which implies that the genome and its environment can operate independently. And of course the angst should be no less for environmental main effects than for those associated with genotype. Again the issue is that of interpretation and an appreciation of what such findings actually do and do not represent.

Twin studies derive estimates of heritability. Such findings are of considerable importance for their own sake, particularly for those interested in issues surrounding familial transmission of vulnerability for illness. An indication of high heritability for a specific trait logically leads to the question of whether genomic variations at the level of sequence might serve as the mechanism for the passage of individual differences in phenotype from parent to offspring (prior to investing valuable research funds in genome-wide searchers, it is indeed useful to establish that the variation in the trait is actually subject to familial transmission). But the idea that estimates of heritability are the *equivalent* of a genetic effect is problematic. First, such estimates ignore Gene × Environment interactions. Indeed, heritability equates with a main effect "genetic" influences only if one assumes no Gene × Environment contribution. Second, the estimate of heritability reflects the importance of genomic mechanisms only if one assumes that there are no other biological mechanisms for inheritance. This is simply untrue. There are multiple potential mechanisms of inheritance, involving, for example, the passage of epigenetic marks (Chong & Whitelaw, 2004) through the germline, the passage of maternal RNA molecules into the embryo, the potential passage of prion proteins from parent to offspring, the biochemical state of the gametes at the time of conception, and the transmission of nutrients, bacteria, or antibodies from maternal circulation to that of the offspring, and so on (Bettegowda & Smith, 2007; Boulinier & Staszewski, 2008; Chong & Whitelaw, 2004; Grindstaff, Brodie, & Ketterson, 2003; Hasselquist & Nilsson, 2009; Rassoulzadegan et al., 2006; Shorter & Lindquist, 2005). Variations in genomic sequence are simply not the only mechanism of inheritance. All of these factors can and do influence the phenotype of the offspring. This is a serious problem for those assuming that heritability equates with main effects of genomic variation.

Apart from the methodological and biological pitfalls with such inferences (Lewontin, 1974; Sokolowski & Wahlsten, 2001; Wahlsten, 1990), the argument presented here is that the notion of a main effect of either ''gene'' or ''environment'' on the development of individual differences in complex traits is biologically fallacious. Instead, the development of the individual is best considered as the emergent property of a constant interplay between the genome and its environment (Gottlieb, 1991, 1997). This article briefly examines how the study of gene activity or expression reveals why main effects models are *biologically* implausible and then reviews studies on the effects of maternal care on glucocorticoid receptor expression in the rat as a model for the understanding one process by which Gene × Environment interactions might operate to influence the development of individual differences.

The Molecular Gene and Its Operation

The challenge within developmental psychology is that of understanding the operation of the genome and how the analysis of nucleotide-based variation can contribute to our understanding of individual differences in brain development and function at the level of cell biology, physiology, and emotional-cognitive states. One obvious way to start is to simply appreciate the role of DNA in cell biology and realize that DNA *directly* codes for molecules, more specifically for ribonucleic acids (RNAs), and not for higher levels of function. While there are indeed statistical relations between variation in nucleotide sequence and that in complex traits, at the level of biology there are no genes for intelligence, depression, athletic abilities, fashion sense, or any other such complex trait. Rather, there are certain variations in genomic sequences that can potentially alter either the DNA product (RNA) or the degree to which the DNA is transcribed (i.e., actively producing its molecular product). There are multiple and complex cellular processes that lie between the DNA sequence and the functional outcome associated with the gene product. The relation between genotype and phenotype, even at the level of cellular molecules, is anything but direct. Thus, the intent of this rather brief section is to simply illustrate the complexity of the processes that mediate genotype–phenotype relations even when considering the most fundamental aspects of gene function—the production of RNAs and protein products.

Throughout portions of this review I will largely focus on one gene, that encoding for the glucocorticoid receptor, both as an exemplar, for which it is rather well suited, and as a subject for our own research. The glucocorticoid receptor belongs to the nuclear receptor superfamily and is transcribed from a single mRNA. The glucocorticoid receptor protein is found both in the cytoplasm and in the nucleus of the cell. The receptor belongs to a class of intracellular proteins referred to as ligand-activated transcription factors. This simply refers to the fact that the binding of the hormone (the ligand) to the receptor alters the configuration of the glucocorticoid receptor, which then permits binding to specific sites on the DNA and the regulation of gene transcription. Glucocorticoids, a hallmark of the endocrine stress response, are hormones secreted by the adrenal cortex that bind to the glucocorticoid receptor to mediate various cellular processes including those involved in cardiovascular activity, appetite, metabolism, immune responses, electrolyte balance, as well as neuronal function and behavior (e.g., Dallman, Akana, Strack, Hanson, & Sebastian, 1995; Dallman, Pecoraro, & la Fleur, 2005; de Kloet, Karst, & Joels, 2008; Heitzer, Wolf, Sanchez, Witchel, & DeFranco, 2007; Kumar & Thompson, 2005; Munck, 2005; Munck, Guyre, & Holbrook, 1984; Sapolsky, Romero, & Munck, 2000; Seckl & Holmes, 2007; Walker, 2007). Thus, the gene encoding the glucocorticoid receptor has multiple, tissue-specific functions. The activation of the glucocorticoid receptor alters gene expression, the number and identity of which depends very much upon the target cell. When not bound by glucocorticoids, the glucocorticoid receptor resides in the cytoplasm of the cell associated with what is termed a chaperone protein (Kumar & Thompson, 2005; Lu & Cidlowski, 2006; McNally, Müller, Walker, Wolford, & Hager, 2000). Binding of glucocorticoids induces conformational changes in the receptor; dissociation from the chaperone proteins; association with another, activated glucocorticoid receptor protein, thus forming a dimer (association of two proteins); translocation into the nuclear compartment; and binding to specific sites on the DNA (Lu & Cidlowski, 2006 and references therein). The activated glucocorticoid receptor can also complex with other proteins, or cofactors, that then modify the effect of glucocorticoid receptor on the expression of target genes. The association of the cofactor may simply modify the ability of the glucocorticoid receptor to access DNA sites, and thus the magnitude of its transcriptional effect. However, the presence of the cofactor may determine the nature of the affected genomic target. Thus, an activated glucocorticoid receptor associated with factor A may influence a different set of genes than the activated glucocorticoid receptor associated with factor B. Thus, the glucocorticoid receptor can affect two different cellular populations in very different ways depending upon the associated cofactor. The function of the glucocorticoid receptor gene product depends upon the context within which it operates. Indeed, the presence of other transcriptional factors can actually determine the direction of the effect of the glucocorticoid receptor on a common genomic target, increasing transcription in one context and decreasing it in another (e.g., Diamond, Miner, Yoshinaga, & Yamamoto, 1990). For example, activation of the glucocorticoid receptor promotes cell survival in liver cells but activates apoptosis (cell death) in thymocytes. Thus, a sequence-based variation in the glucocorticoid receptor could (and indeed does) have exactly the opposite effect on two different cellular populations. Of course, not all contextual effects are quite so dramatic. But the influence of such cofactors reveals a complexity that suggests that the consequences of even a highly functional sequence variation in the glucocorticoid receptor gene, as an example, will be determined by the cellular mileu in which the glucocorticoid receptor gene is operational. Some cells would inevitably be more affected than others. The presence and activity of such cofactors is regulated by a variety of extra- and intracellular signals and forms an important feature of the context within which glucocorticoid receptor activity is defined. This rather complicates the study of genotype–phenotype relations and the plausibility of simple main effects of either genome or environment at the level of cell biology. Rather, such processes suggest that the effect of genomic sequence variation is understood only in terms of its interaction with environmental signals represented in the cellular context. Such signals, of course, would also reflect sequence variation in other genomic regions. Since the transcriptional cofactors that influence glucocorticoid receptor activity are constantly regulated by the internal and external environment, the functional implications of a sequence-based variation in the glucocorticoid receptor gene are inexorably linked to context.

The glucocorticoid receptor can also alter gene expression and cellular function through processes that do not involve the interaction of the receptor with DNA. Intracellular proteins interact to form complexes. In certain cases, such interactions inhibit the action of one of the partners. One of the primary biological effects of the activated glucocorticoid receptor is to dampen inflammation (Munck, 2005; Munck et al., 1984). This effect involves, in part, the interaction of the glucocorticoid receptor with another protein, NFKß (e.g., Nissen & Yamamoto, 2000), which is a major participant in the activation of inflammatory responses. The binding of the glucocorticoid receptor renders NFKß unable to access its DNA targets, thus muting the inflammatory reaction. However, this glucocorticoid receptor effect is apparent only if there is an elevation in NFKß. Thus, the effects of either a genomic or environmental influence would depend upon the immunological status of the organism, further reflecting the importance of context. The function of the glucocorticoid receptor gene with such protein–protein interactions further illustrates why notions of main effects of gene or environment at the level of biological mechanism are untenable.

Figure 1 outlines the organization of the glucocorticoid receptor gene in the rat, which was cloned in large part by the group of Yamamoto (Miesfield et al., 1984) with a recent addition from our group in collaboration that of Jonathan Seckl (McCormick et al., 2000). The organization of the gene is similar in rat and human (Nobukuni, Smith, Hager, & Detera-Wadleigh, 1995; Turner & Muller, 2005). The glucocorticoid receptor gene comprised nine exons (an exon is a region of DNA that contributes directly to an mRNA molecule). Exons 2–9 are coding regions that produce mRNA for amino acids sequences included in the glucocorticoid receptor protein (as in DNA–RNA–protein). Exon 1 is a

Figure 1. A schema describing the organization of the rat glucocorticoid receptor gene including nine exon regions.
Note. Exons 2–9 participate in the coding of the glucocorticoid receptor protein. Exon 1 comprised multiple regions, each of which is capable of activating gene transcription (i.e., promoter sequences). The various exon 1 promoters' actions are tissue-specific, with evidence suggesting that certain promoters are more active in areas such as liver or thymus, and others more active in brain (e.g., exon 17; based on McCormick et al., 2000; see Turner & Muller, 2005, for comparable data in humans). The consensus binding site for NGFI-A lying within the exon 1_7 promoter is highlighted. NGFI-A = nerve growth factor-inducible factor A.

large region containing a number of nucleotide sequences that are represented in the glucocorticoid receptor mRNA, but do not code for protein. This exon 1 region contains a number of regulatory elements, the activation of which alters the level of glucocorticoid receptor gene transcription. This exon 1 region is similarly organized in humans (Turner & Muller, 2005; see Zhang, Haws, & Wu, 2004, for examples of similar genomic organization). In the rat, each of the individual exon 1 segments displayed in Figure 1 contains a region that activates gene transcription (i.e., a transcriptional start site; McCormick et al., 2000) and is therefore referred to as a "promoter." Thus, intracellular signals, referred to as transcription factors, bind to different regions on the exon 1 promoters to activate or repress the transcription of the glucocorticoid receptor gene. Figure 1 shows a small segment from the exon 1_7 promoter for the rat glucocorticoid receptor gene that binds the transcription factor nerve growth factor-inducible factor A (NGFI-A; Crosby, Puetz, Simburger, Fahrner, & Milbrandt, 1991).

The exon 1 region contains a number of promoters, and this complex level of regulation is essential for glucocorticoid receptor function. The glucocorticoid receptor gene is potentially active in virtually every cell in the body, with different functions across various cell types. In the fetal mammal, for example, the activation of the glucocorticoid receptor induces lung surfactant, a protein essential for the transition to a gaseous environment that marks birth. This effect is the basis for the glucocorticoid therapy of premature infants. Increasing glucocorticoid receptor function in pulmonary tissues in late fetal life is essential. Not so in the brain. Activation of glucocorticoid receptors in the mammalian forebrain is associated with a decrease in neurogenesis (Uno, Tarara, Else, Suleman, & Sapolsky, 1989) and synaptic plasticity (de Kloet et al., 2008; McEwen, 2007). Similar catabolic effects are apparent in several other tissues (Munck et al., 1984; Sapolsky et al., 2000). The ideal scenario is that of increasing glucocorticoid receptor expression in the lung while muting that in neurons and other active sites of growth (Bronnegard & Okret, 1991; Sapolsky & Meaney, 1986). Such tissue-specific expression of the glucocorticoid receptor gene is probably accomplished through the activation of different transcriptional promoters in various tissues. Indeed, different promoters are associated with the activation of the glucocorticoid receptor in lung, liver, thymus, and brain (McCormick et al., 2000). It is therefore possible to increase the expression of the glucocorticoid receptor in one tissue while leaving it unaltered or even decreased in another. Thus, a nucleotide-based variant in a glucocorticoid receptor promoter region might lead to altered transcription of the glucocorticoid receptor gene in one tissue, while the activation of the same gene in a different tissue is completely unaffected. The resulting genotype–phenotype interaction would then depend upon whether the trait under study is dependent upon a cellular population that employs the affected promoter sequence.

There is also variation of glucocorticoid receptor gene function at the level of the protein product (Lu & Cidlowski, 2006). Exons 2–9 encode multiple variants of the glucocorticoid receptor. Two of the variants (or isoforms), the α- and β-forms of the glucocorticoid receptor, are identical for the first 727 amino acids, beyond which they differ. Glucocorticoid receptor α has an additional 50 amino acids not contained in the ß-variant. The ß-variant has 15 distinct amino acids. The classic effects of glucocorticoids on gene expression are mediated through glucocorticoid receptor α. Glucocorticoid receptor ß seems to bind to glucocorticoid receptor α and to block its effects on gene transcription (Lu & Cidlowski, 2006). Indeed, increased expression of glucocorticoid receptor ß produces glucocorticoid resistance. What is remarkable is that two seemingly antagonistic proteins are actually encoded from the same gene! Further complicating the picture is the finding that the glucocorticoid receptor ß-variant is produced in only a subset of cells. The production of glucocorticoid receptor variants, and thus of glucocorticoid receptor gene, is entirely dependent upon the cellular context within which the gene operates.

The production of glucocorticoid receptor protein variants is not limited to the α- and ß-isoforms. More recent studies reveal at least eight different versions of the glucocorticoid receptor a protein, each produced from the same gene and even the same mRNA (Lu & Cidlowski, 2006). These glucocorticoid receptor α-isoforms are differentially distributed across various tissues and differ in their transcriptional activity on target genes. Certain genomic targets are regulated by all of the various glucocorticoid receptor α-isoforms, although transcription is regulated to a greater extent by some isoforms than by others. But some genes are regulated only by certain isoforms. In no case is this diversity in the genomic product associated with variation in nucleotide sequence. This complexity is an inherent feature of the glucocorticoid receptor system.

This brief review considers only the variation in the glucocorticoid receptor protein itself. If we factor into consideration the potential for such variation together with the multiple cofactors, each of which can alter glucocorticoid receptor function, the potential for diversity in signaling becomes substantially greater. If genotype–phenotype relations are so remarkably intricate at the level of protein, then imagine the complexity at the level of physiology and behavior! It is critical that we appreciate the degree to which the activity of the gene is dependent upon the cellular context within which it functions and to appreciate that this same context is also subject to the influences of sequence variations in other genes that operate within the same network. Both the form and the function of the protein product are defined by context. The function of the gene can only be fully understood in terms of the cellular environment in which it operates. And the cellular environment, of course, is dynamic, changing constantly as a result of signals from other cells, including those that derive from events occurring in the external environment. Ultimately, function can only be understood in terms of the interaction between environmental signals and the genome.

Gene Transcription

The most compelling evidence for the predominance of Gene × Environment interactions in cellular function emerges from the study of gene transcription. The transcription of a gene is a highly regulated event. At the heart of this process lies a class of proteins referred to as transcription factors (and see earlier). As the name implies, these proteins have the ability to bind to regulatory elements of the gene (e.g., see the exon 1 region of the glucocorticoid receptor gene) and to activate or repress gene transcription. Importantly, the expression and/or activation of the transcription factors themselves are dynamically regulated by environmental signals. Many of the earliest cellular responses to environmental stimuli involve either the activation of preexisting transcriptional signals through, for example, phosphorylation at specific sites, or the rapid synthesis of proteins (e.g., immediate early gene products) that then serve to regulate the activity of other genes. Thus, the binding of transcription factors to DNA sites is the biological machinery of the dynamic Gene × Environment interactions that result in altered rates of gene transcription.

Figure 1 portrays the organization of the glucocorticoid receptor gene. The schema is actually somewhat misleading. For reasons of graphic simplicity, we often describe the organization of a gene or the interactions between transcription factors and DNA as if the DNA were a linear molecule to which transcription factors gain unimpeded access. The reality of protein–DNA interactions is quite different. Figure 2 presents the classic crystallographic analysis of the organization of DNA (Luger, Mader, Richmond, Sargent, & Richmond, 1997). DNA is organized into units referred to as nucleosomes, each of which contains about 145–150 base pairs wrapped around a core region of histone proteins (Turner, 2001). The histones and DNA together are referred to as chromatin; the nucleosome is the organization of chromatin. Under normal conditions there is a tight physical relation between the histone proteins and its accompanying DNA, resulting in a rather closed nucleosome configuration. This restrictive configuration is maintained, in part, by electrostatic bonds between the positively charged histones and the negatively charged DNA. The closed configuration impedes transcription factor binding and is associated with a reduced level of gene expression. The activation of gene expression commonly requires chemical modifica-

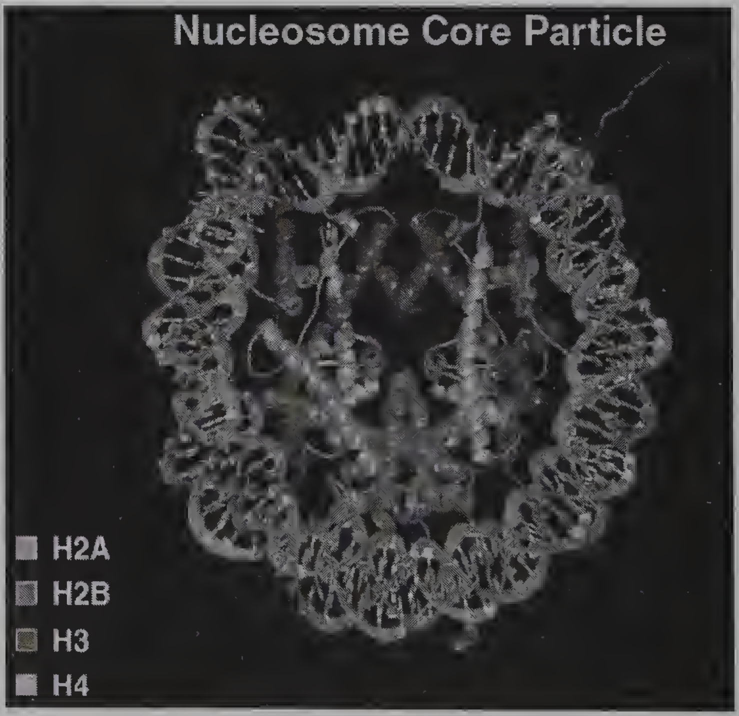

Figure 2. Crystallographic image of the nucleosome showing 146 bp wrapped around a histone complex that comprised histone 2A, 2B, 3, and 4 proteins (from Luger et al., 1997).
Note. The tight configuration is maintained, in part, by electrostatic bonds. Modifications, such as acetylation, to the histone regulate transcription factor binding and occur primarily at the histone tails protruding out of the nuclesome (pictured is the tail of histone 3).

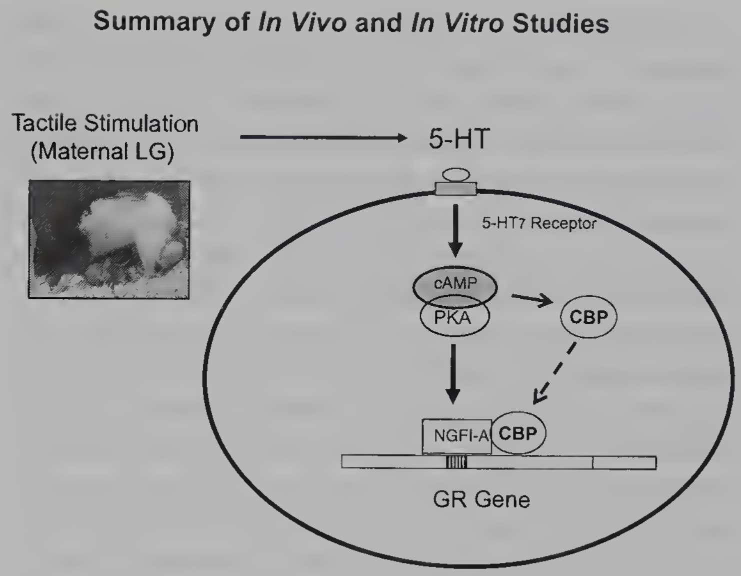
tion of the chromatin that occurs on the histone proteins.

Histone Modifications

Chromatin remodeling is required for increased transcription factor binding to regulatory sites on the DNA and the activation of gene expression. The dynamic alteration of chromatin structure is achieved through modifications to the histone proteins at the "tail" regions that protrude outside of the nucleosome (Figure 2). This process is achieved through a series of enzymes that bind to the histone tails and modify the local chemical properties of specific amino acids along the tail (Grunstein, 1997; Hake & Allis, 2006; Jenuwein & Allis, 2001). The histone tails are chains of amino acids that include lysines and arginines that are primary targets for modification. For example, the enzyme histone acetyltransferase "transfers" an acetyl group onto specific lysines on the histone tails. The addition of the acetyl group diminishes the positive charge, loosening the relation between the histones and DNA, opening the chromatin, and improving the ability of transcription factors to access DNA sites. Thus, histone acetylation at specific lysine sites is commonly associated with active gene transcription. The functional antagonists of the histone acetyltransfereases are a class of enzymes known as histone deacetylases (HDACs). These enzymes remove acetyl groups and prevent further acetylation, thus serving to maintain a closed chromatin structure, decreasing transcription factor and gene expression. The reader should note that there are actually multiple modifications to histone tails including methylation (in this case on the histones), phosphorylation, ubiquitination, and so on. For the sake on simplicity, the discussion is limited to histone acetylation or deacetylation.

Regulation of Glucocorticoid Receptor Expression

Figure 3 summarizes the effect of the neurotransmitter serotonin (5-hydroxytryptamine [5-HT]) on glucocorticoid receptor gene transcription in hippocampal neurons (Mitchell, Betito, Rowe, Boksa, & Meaney, 1992; Mitchell, Rowe, Boksa, & Meaney, 1990; Weaver et al., 2007). This effect is dependent upon the binding of the transcription factor NGFI-A to a specific binding site on the exon 1_7 GR promoter. We can precisely define the importance of this interaction. For example, mutating a single nucleotide, in this case simply exchanging a cytosine for an adenine, in the region of the promoter that normally binds NGFI-A abolishes the ability of NGFI-A to associate with the exon 1_7 promoter and eliminates the effect of NGFI-A on gene transcription (Weaver et al., 2007). However, the ability of NGFI-A to bind to the exon 1_7 promoter is regulated by another protein, a cofactor, the concentration of adenosine 3,5-monophosphate (cAMP)-response element-binding (CREB) protein, that is, activated by the same 5-HT–cAMP/PKA (protein kinase A) signaling cascade (Figure 3). The CREB-binding protein is a histone acetyltransferase. The resulting increase in the association of the CREB-binding protein with the exon 1_7 promoter is accompanied by an increase in the acetylation of a specific lysine on the tail of histone 3 of the exon 1_7 promoter (Weaver et al., 2004; Weaver et al., 2007). Thus, 5-HT activates both NGFI-A and the CREB-binding protein, which appear to associate with one another prior to DNA binding. The CREB-binding protein acetylates histones associated with the exon 1_7 promoter, enhancing the ability of NGFI-A to bind and activate gene transcription.



Summary of *In Vivo* and *In Vitro* Studies

Figure 3. A summary of in vivo studies with hippocampal tissue samples from neonates and in vitro studies using primary hippocampal cell cultures.
Note. In vivo, an increased frequency of pup LG associates with hippocampal 5-HT turnover, activation of a 5-HT7 receptor positively coupled to cAMP and cyclic nucleotide-dependent kinases (PKA), and the induction of NGFI-A expression. In vivo, increased pup LG or artificial tactile stimulation induces NGFI-A expression as well as that of the CREB-binding protein, both of which show greater binding to the exon 17 promoter in the neonatal offspring High- compared with low-LG mothers. Results of in vitro studies show that blockade of cAMP, PKA, or NGFI-A abolish the effect of 5-HT of glucocorticoid receptor expression. cAMP = concentration of adenosine 3,5-monophosphate; CREB-binding protein = cAMP-response element-binding protein; 5-HT = 5-hydroxytryptamine; LG = licking/grooming; NGFI-A = nerve growth factor-inducible factor A; PKA = protein kinase A.

Serotonin is a classic neurotransmitter that responds dynamically to environmental signals. This effect reflects the dependence of gene transcription on signals that derive from environmental events (note the relevant environmental event may be internal or external to the organism; e.g., a change in the availability of glucose, an electrical impulse, or a social interaction). Thus, the consequences of a variation in DNA sequence for phenotype will depend upon environmental signals. The genomic variant is relevant for phenotype only to the extent that the gene is actually expressed and participating in cellular function. If a particular tissue were to reveal a genomic variant in a region of the DNA that is transcriptionally inactive, then the implications for phenotype are minimal. The degree to which a genomic variant influences phenotype will depend upon the cellular context. Likewise, to the extent that an inherited genomic variant influences the capacity for transcription, then the influence of the environmental signal on phenotype will be affected by variation in nucleotide sequence. Such considerations showcase the interdependence of gene and environment.

Gene × Environment Interactions: The Case of the 5-HT Transporter

One of the best-studied genomic variations in biological psychiatry is that of the polymorphism in the promoter region of the *SLC6A4* gene that encodes for the 5-HT transporter (5-HTTP). The synaptic activity of 5-HT is terminated by reuptake into presynaptic terminals, which occurs via the 5-HTTP protein. Serotonin is a critical neurotransmitter in the regulation of emotional states (Lucki, 1998) and a major target for medications designed to treat a range of affective disorders (Blier & de Montigny, 1999; Gross & Hen, 2004). The gene for the 5-HTTP in humans shows a relatively common polymorphism characterized by a variable repeat sequence in the promoter region resulting in two common alleles: the short (*S*) variant comprising 14 copies of a 20–23 base-pair repeat unit, and the long (*L*) variant comprising 16 copies (Lesch et al., 1996).

The 5-HTTP promoter sequence polymorphism associates with differential transcription of the 5-HTTP gene, with more efficient expression from the *L* allele (Greenberg et al., 1999; Lesch et al., 1996). More recent studies suggest that further variation lying within the *L* allele also affects 5-HTTP gene function, resulting in subtypes of the *L* allele (Hu et al., 2005). The early studies of the functional correlates of the 5-HTTP promoter polymorphism as well as subsequent meta-analyses (Sen, Burmeister, & Ghosh, 2004; Schinka, Busch, & Robichaux-Keene, 2004; but also see Munafo, Clark, & Flint, 2005) reveal a statistical association with neuroticism, which is elevated among individuals that carry at least one copy of the *S* allele. Since neuroticism predicts an increased risk for affective disorders (Hettema, Neale, Myers, Prescott, & Kendler, 2006; Kendler, Kuhn, & Prescott, 2004), it is not surprising that the 5-HTTP promoter polymorphism is at least weakly associated with disorders of emotional function, namely, depression and anxiety (Canli & Lesch, 2007; Hariri, Emily, Drabant, & Weinberger, 2006).

Affective disorders associate with altered activity in the amygdala (Davis, 2006; Gorman, Kent, Sullivan, & Coplan, 2000; LeDoux, 2000; Meaney, LeDoux, & Leibowitz, 2008; Pérez-Edgar & Fox, 2005), a primary brain structure for emotional states of fear as well as a major target for 5-HT projections from the raphé nuclei. The expression of fear in rodents is inhibited by 5-HT activity in the hippocampus and amygdala (Stutzmann & LeDoux, 1999), and animals bearing mutations of 5-HT1A receptors show enhanced fearfulness (Gross & Hen, 2004). Aversive stimuli activate the amygdala in humans (LaBar et al., 1995; LaBar et al., 1998; Morris, Ohman, & Dolan, 1998) and individual differences in trait anxiety predict the response of the amygdala to threatening stimuli (Etkin, Egner, Peraza, Kande, & Hirsch, 2005; Etkin et al., 2004). Individuals carrying an *S* variant of the 5-HTTP promoter polymorphism show increased activation of the amygdala while processing fearful or angry faces (Hariri et al., 2002; Hariri et al., 2005; Pezawas et al., 2005). Similar effects of the 5-HTTP promoter polymorphism are obtained in subjects during processing of negative relative to neutral pictures (Heinz et al., 2005) or words (Canli et al., 2006). Moreover, the *S* allele of the 5-HTTP promoter is associated with increased activity at rest in both the amygdala and the hippocampus (Canli & Lesch, 2007).

An additional feature of anxiety is that of decreased inhibitory prefrontal regulation of evoked activity in the amygdala (Shin et al., 2004, 2005). Affective disorders associate with decreased volume in the subgenual region of the anterior cingulate cortex (Drevets et al., 1997), which projects to and regulates activity in the amygdala (Maren & Quirk, 2004). Gray matter volume in the subgenual anterior cingulate cortex is reduced in carriers of the *S* variant of the 5-HTTP promoter polymorphism. In addition, individuals bearing the *S* promoter variant show decreased functional connectivity between the amygdala and anterior cingulate cortex (Pezawas et al., 2005), which could serve as the basis for the increased amygdala response to negative stimuli.

Since genomic variations are potentially operative at any time over the lifespan, it is interesting to consider the possibility that the 5-HTTP polymorphism could alter 5-HT activity during periods of neural development. Thus, Pezawas et al. (2005) proposed that the association between the 5-HTTP promoter polymorphism and vulnerability to depression reflects a developmental process that affects the structural connectivity and functional interactions within a neural circuit that regulates emotional reactivity and fear. They further proposed that these functional deficits could be exacerbated by environmental adverse experiences, possibly through an impaired capacity to regulate affective states during periods of adversity. Such an effect would be expected to result in an interaction between gene and environment that renders individuals vulnerable to affective disorders. There is considerable evidence in support of this developmental hypothesis. Studies with rodent models reveal a profound influence of 5-HT activity on neuronal development, including the sprouting of axonal processes. Hen and colleagues (Gross et al., 2002) showed that a null mutation of the 5-HT1A in mice associates with increased fearfulness. This knockout model, like that of human sequence polymorphisms, reveals effects from conception onward to the time of behavioral assessment. It is therefore unclear as to whether the associated change in phenotype reflects a developmental influence, an effect on neurotransmission at the time of assessment, or both. Hen's lab (Gross & Hen, 2004; Gross et al., 2002) resolved this issue by producing a conditional knockout model in which the gene that encodes for the 5-HT1A receptor is rendered inoperative only during selected periods over the lifespan of the mouse. The findings reveal that the condition in which the 5-HT1A receptor gene is muted for only during the first 3 weeks of life completely recapitulates the increased fearfulness observed in animals in which the 5-HT1A receptor was knocked out for the entire life of the animal. These findings suggest that genomic variants that alter 5-HT function can act during early development to regulate neural circuitry that mediates the expression of fear. Moreover, variants of the gene for the 5-HTTP are associated with negative temperament in infancy (Auerbach et al., 2002; Ebstein, 2003, 2006), further suggesting that the consequences of 5-HT alterations appear in early life. Here again, however, there is environmental modulation of the genotype–phenotype relation. Fox et al. (2005) reported that the quality of the maternal environment interacted with the 5-HTTP promoter genotype to determine behavioral inhibition in children.

Fox et al.'s (2005) report is representative of a growing body of studies revealing Gene × Environment interactions in emotional and cognitive development. Suomi, Bennett, and colleagues described a brilliant example of such gene–environment interdependence in the rhesus monkey (Bennett et al., 2002; Champoux et al., 2002; Suomi, 2006). The rhesus monkey shows a polymorphism in the 5-HTTP promoter that is comparable in form and function to that in humans such that the *S* 5-HTTP promoter variant in the monkey is also associated with decreased 5-HTTP levels in brain (Lesch et al., 1997). Likewise, the 5-HTTP promoter polymorphism affects both 5-HT metabolism and emotional function in the monkey. Monkeys bearing the *S* version of the 5-HTTP promoter polymorphism show reduced 5-HT activity, increased impulsivity, and are more aggressive than animals bearing the longer version of the promoter variant (Bennett et al., 2002; Champoux et al., 2002). However, the genotype–phenotype relation is strongly influenced by the rearing environment. The phenotypic differences described earlier are apparent among animals separated from their mothers and reared in peer–peer groups. In contrast, among animals reared by their mothers, the differences in phenotype are actually slightly reversed such that animals with the *S* variant of the 5-HTTP promoter show modestly greater 5-HT activity and are less impulsive and aggressive than those carrying the longer promoter variant. In these studies, the genotype–phenotype relations depended completely upon the rearing environment. Similar effects are apparent in the mouse where there is an interaction between a disruption of the 5-HTTP gene and the quality of maternal care on neural systems associated with fear behavior (Carola et al., 2008).

A series of landmark studies (e.g., Caspi & Moffit, 2006; Caspi et al., 2003) provide a parallel set of findings in human populations. In these studies, as shown in previous research, childhood maltreatment increases the probability of an episode of major depression. However, this effect is only apparent among individuals that bear at least one copy of the *S* 5-HTTP promoter allele. Individuals homozygous for the *L* promoter variant show no increase in the probability of depression despite the experience of childhood maltreatment (see Caspi & Moffit, 2006, for a review of other, compelling examples of such Gene × Environment interactions). A more recent study shows evidence for the same Gene × Environment interaction in defining individual differences in neural functions that associate with depression (Canli et al., 2006). There is also evidence of a comparable Gene × Environment effect examining polymorphisms in other genes implicated in 5-HT neurotransmission (Jokela et al., 2007). In this case, the polymorphism in question is a SNP in the *5HTR2A* gene that encodes for the 5-HT2A receptor that is also linked to mood disorders. The authors found a significant interaction between the *5HTR2A* genotype and the quality of maternal care in defining the level of depressive symptoms.

The Caspi et al. (2003) finding of an interaction between the promoter polymorphism and either life stressors or childhood maltreatment has been replicated (Kaufman et al., 2004; Kendler, Kuhn, Vittum, Prescott, & Riley, 2005), and other studies suggest further moderation by gender (Eley et al., 2004; Grabe et al., 2005) or social support (Kaufman et al., 2004). Two studies (Gillespie, Whitfield, Williams, Heath, & Martin, 2005; Surtees et al., 2006) failed to replicate this Gene × Environment interaction effect. However, we need to appreciate that an interaction between a *single* genomic variant and a broadly characterized environmental condition at one stage of life is still a rather narrow focus on the complex pathophysiology of mental disorders. Genes encode for RNAs and proteins that operate in complex networks within cell signaling pathways. Such networks form the basis for the interaction of gene products that are then revealed as gene–gene interactions in studies of genomic variations, including data sets from genome-wide association studies. A major advance in genetics is the emergence of computational approaches that apply a biologically informed, statistical analysis of the interactions between functionally related genes. Such bioinformatic approaches feature the description of gene networks, involving multiple genomic targets and their variations. We can thus anticipate studies of Gene Network × Environment interactions.

Arguments for the interdependence of gene and environment should be familiar to those in developmental psychology. Belsky (1997) and Rutter (2007) argue from the other point of view that environmental forces, such as familial influences, will not affect all children equally and that an obvious source of differential sensitivity lies in genomic variation. In the nonhuman primate studies cited earlier, animals bearing the *L* variant of the 5-HTTP promoter polymorphism are markedly less sensitive to peer versus maternal rearing than those carrying the *S* promoter variant (at least with respect to the measures used in these studies). The same argument could be made for the Caspi et al. (2003) findings that reveal an increased risk for depression associated with child maltreatment among those bearing *S/S* 5-HTTP promoter variants. Indeed, one might well imagine that certain genomic variants alter neuronal function of the child, affecting the response to environmental conditions. Studies examining the children with a polymorphism on the *DRD4* gene that encodes a receptor for the neurotransmitter dopamine bear on this point. This genomic variant is associated with differences in attachment (Gervai et al., 2007; Lakatos et al., 2002) as well as infant responses to novelty (Lakatos et al., 2003). The *DRD4* polymorphism interacts with the quality of parenting to determine the level of internalizing and externalizing behavior in children (Propper, Willoughby, Halpern, Carbone, & Cox, 2007). Moreover, the same polymorphism determines the effect of a parent-training intervention targeting maternal sensitivity on the level of externalizing behavior in children (Bakermans-Kranenburg, Van IJzendoorn, Pijlman, Mesman, & Juffer, 2008). In these studies, the genotype of the child determined the response to parenting. Likewise, considering the evidence for the effects of genomic variants on emotional functions in children, genomic variation might operate within specific familial settings (e.g., Fox et al., 2005) to influence the behavior of the child and thus the quality of the interactions with caregivers. The 5-HTTP polymorphism associates with differences in infant temperament and reactions to novelty (Auerbach et al., 1999; Ebstein, 2006; Lakatos et al., 2003), which in turn predicts sensitivity to parental influences (Belsky, 1997). Although the point is less emphasized in this article, the Gene × Environment perspective argues no less forcefully that environmental effects must be considered within the genomic context of the individual. The interdependence of gene and environment is bidirectional.

These findings underscore the importance of Gene × Environment interactions, and the studies with the rhesus monkey suggest that the developmental consequences of such interactions persist into adulthood. This consideration simply reflects the long-standing interest of psychologists on the potential influence of early experience (Gottlieb, 1991, 1997), particularly those involving the interaction of the parent and child, on phenotypic development. In the preceding sections, we considered the molecular mechanisms that underlie Gene × Environment interactions with respect to immediate and transient changes in gene expression. But what are the mechanisms that might account for the enduring effects of environmental conditions on gene expression? How might parental influences stably alter phenotype? Could such effects involve the "programming" of gene expression? How might such stable influences occur? A response to such questions requires an understanding of the physical properties of Gene × Environment interactions that produce enduring effects on brain function.

Environmental Programming of Gene Expression

Studies in developmental psychobiology and physiology are replete with examples of the environmental programming of gene expression. Such studies commonly report that a variation in the early environment associates with changes in gene expression and function that persist into adulthood and thus well beyond the duration of the relevant environmental event. In the rat, for example, prenatal nutrient deprivation or enhanced exposure to hormonal signals associated with stress can stably alter, or program, the transcription of genes in the liver and other sites that are associated with glucose and fat metabolism, including the gene for the glucocorticoid receptor (Bateson et al., 2004; Gluckman & Hanson, 2004, 2007; Meaney, Szyf, & Seckl, 2007; Seckl & Holmes, 2007). These findings are assumed to represent instances in which the operation of a genomic region in adulthood varies as a function of early environmental influences. The results of recent studies suggest that such "programming" effects can derive from Gene × Environment interactions in early life that lead to a structural alteration of the DNA, which in turn mediates the effects on gene expression as well as more complex levels of phenotype (Meaney & Szyf, 2005; Meaney et al., 2007). These studies have been performed in rodents but were inspired by the vast literature reporting the pervasive effects of family environment on health outcomes in humans.

Epidemiological studies reveal the importance of family function and early life events as predictors of health in adulthood (Felitti et al., 1998; Leserman et al., 1996; Lissau & Sorensen, 1994; McCauley et al., 1997; Repetti, Taylor, & Seeman, 2002; Russak & Schwartz, 1997; Seckl, 2001). As adults, victims of childhood physical or sexual abuse, emotional neglect and harsh, inconsistent discipline are at considerably greater risk for mental illness, as well as for obesity, gastrointestinal illness, diabetes, and heart disease. "Stress diathesis" models are proposed as explanations for the relation between early experience and health (e.g., Gorman et al., 2000; Heim & Nemeroff, 2001; McEwen, 2003; Meaney, 2001; Meaney et al., 2007; Repetti et al., 2002; Seckl & Meaney, 1994). These models suggest that adversity in early life alters the development of neural and endocrine responses to stress in a manner that predisposes individuals to disease. Adversity or decreased quality of parental investment appears to directly increase the magnitude of emotional, autonomic, and endocrine responses to stress (collectively referred to here as *defensive responses*). Diathesis describes the interaction between development, including the potential influence of genetic variations at the level of sequence, and the prevailing level of stress in predicting health outcomes. Such models have considerable appeal and could identify both the origins of illness and the nature of the underlying vulnerability (as well as resilience). Moreover, such models have the virtue of providing a logical bridge between psychosocial (e.g., family function) and biological (endocrine responses to stressors) levels of analyses in understanding health outcomes.

A critical assumption in the stress diathesis models is that the increased expression of defensive responses endangers health. The idea has considerable support in clinical physiology (Chrousos & Gold, 1992; Dallman et al., 2005; McEwen, 2007). Defensive responses to stress are adaptive. Neural signals associated with the perception of the stressor increase the release of stress hormones into the bloodstream, including glucocorticoids from the adrenal gland and catecholamines, particularly norepinephrine, from the sympathetic nervous system. The combined actions of these hormones increase the availability of energy substrates, such as those derived from fat and glucose metabolism. Such effects maintain the normal cellular function and organ efficiency. These actions protect against catastrophes such as hypotensive shock. The release of catecholamines in the brain increases vigilance and provokes states of fear, and enhances avoidance learning and fear conditioning, which can serve to reduce the chances of further encounters with the same conditions.

Defensive responses are the logical outcome of the stress-induced changes in activity in the brain and endocrine organs, and are defined by increases in the synthesis and release of glucocorticoids and catecholamines (Dallman et al., 1995; Munck et al., 1984; Rosen & Schulkin, 1998; Sapolsky et al., 2000). However, there is a cost associated with persistent activation of these same responses: chronically enhanced emotional arousal, sustained increases in blood sugars and fats, possible hyperinflammation, disruption of sleep and normal cognitive function, among others (Chrousos & Gold, 1992; Dallman et al., 2005; McEwen, 2007; Sapolsky et al., 2000; Walker, 2007). Thus, chronic activation of defensive responses can indeed predispose individuals to illnesses such as diabetes, heart disease, mood disorders, and so on. Not surprisingly, studies in behavioral medicine reveal that individuals with enhanced stress reactivity are at greater risk for such forms of chronic illness. However, it is also important to note that insufficient activation of defensive responses under conditions of threat also compromises health and is associated with chronic fatigue, chronic pain, posttraumatic stress disorder, and hyperinflammation (Munck et al., 1984; Raison & Miller, 2003; Yehuda & Bierer, 2008). We walk a fine line here. And this underscores the importance of an appropriate level of stress reactivity for the individual, one sufficient to ensure the maintenance of function during adversity, but not so excessive as to promote chronic illness. What is appropriate, of course, will vary depending upon the prevailing level of environmental demand. There is no single, ideal level of stress reactivity across all populations.

Individual Differences in Defensive Responses

In the late 1950s and early 1960s, psychologists Gig Levine and Victor Denenberg (Denenberg, 1964; Levine, 1970) reported that postnatal handling (or infantile stimulation) of infant rodents decreased the magnitude of both behavioral and hypothalamic–pituitary–adrenal (HPA) responses to stress in adulthood. These findings demonstrated the influence of the early environment over the development of rudimentary defensive responses to threat. The importance of such findings in this era should not be underestimated. This was a period when defensive responses were considered as ''innate,'' developing well outside the realm of experiential influence. Levine and others later suggested that the effects of handling were actually mediated by changes in maternal care. Thus, handling of the pups was thought to alter the behavior of the mother, which was then critical for the ''handling'' effects. The handling paradigm involves exposure of the neonate to a complex set of stimuli, including that of a novel physical environment (Tang, Akers, Reeb, Romeo, & McEwen, 2006). Nevertheless, postnatal handling of rat pups does indeed increase the licking/grooming (LG) of pups by the mother (e.g., Lee & Williams, 1977; Liu et al., 1997). Pup LG is a major source of tactile stimulation for the neonatal rat that regulates endocrine and cardiovascular function in the pup (Hofer, 2005; Levine, 1994; Schanberg, Evoniuk, & Kuhn, 1984). The question then was whether such variations in pup LG might directly alter the development of individual differences in defensive responses.

Subsequent findings revealed considerable evidence for the effect of maternal care on the behavioral and endocrine responses to stress in the offspring. One approach was to simply examine the consequences of naturally occurring variations in pup LG among lactating rats independent of any experimental manipulation. Among lactating rats there are considerable individual differences in the frequency of pup LG that are stable over the reproductive lifetime of the female (Champagne, Francis, Mar, & Meaney, 2003). The results of longitudinal studies are consistent with the Levine (1970) hypothesis. The male or female adult offspring of mothers that naturally exhibit increased levels of pup LG (i.e., high-LG mothers) show more modest behavioral and endocrine responses to stress compared to animals reared by low-LG mothers (Caldji et al., 1998; Francis, Diorio, Liu, & Meaney, 1999; Liu et al., 1997; Menard, Champagne, & Meaney, 2004; Toki et al., 2007; Weaver et al., 2004; Zhang et al., 2006). Specifically, the offspring of high-LG mothers show reduced fearfulness and more modest HPA responses to stress. Cross-fostering studies, where pups born to high-LG mothers are fostered at birth to low-LG mothers (and vice versa), suggest a direct relation between maternal care and the postnatal development of individual differences in behavioral and HPA responses to stress (Caldji, Diorio, & Meaney, 2003; Caldji, Francis, Sharma, Plotsky, & Meaney, 2000; Francis et al., 1999; Weaver et al., 2004). In these studies, the rearing mother determined the phenotype of the offspring. Thus, variations within a normal range of parental care can dramatically alter phenotypic development in the rat.

The effects of maternal care on the development of defensive responses to stress in the rat involve alterations in the function of the corticotrophin-releasing factor (CRF) systems in selected brain regions (Figure 4). The CRF system furnishes the critical signal for the activation of behavioral, emotional, autonomic, and endocrine responses to stressors (Bale & Vale, 2004; Koob, Heinrichs, Menzaghi, Pich, & Britton, 1994; Plotsky, Cunning-

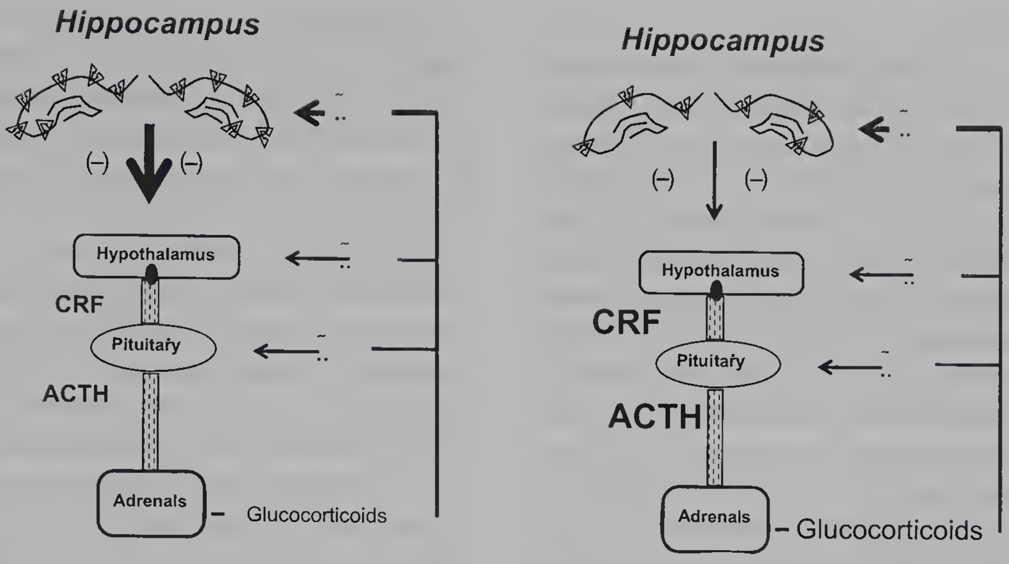


Figure 4. A schema outlining the function of the hypothalamic–pituitary–adrenal axis, the nexus of which are the corticotropin-releasing factor (CRF) neurons of the paraventricular nucleus of the hypothalamus.
Note. CRF is released into the portal system of the anterior pituitary stimulating the synthesis and release of adrenocorticotropin (ACTH), which then stimulates adrenal glucocorticoid release. Glucocorticoids act on glucocorticoid receptors in multiple brain regions, including the hippocampus, to inhibit the synthesis and release of CRF (i.e., glucocroticoid negative feedback). The adult offspring of high-LG mothers, by comparison to those of low-LG dams, show (a) increased glucocorticoid receptor expression, (b) enhanced negative-feedback sensitivity to glucocorticoids, (c) reduced CRF expression in the hypothalamus, and (d) more modest pituitary–adrenal responses to stress. LG = licking/grooming.

ham, & Widmaier, 1989). As adults, the offspring of high-LG mothers show decreased CRF expression in the hypothalamus, as well as reduced plasma adrenocorticotropin (ACTH) and glucocorticoid responses to acute stress by comparison to the adult offspring of low-LG mothers (Francis et al., 1999; Liu et al., 1997; Weaver et al., 2004; Weaver et al., 2005). Circulating glucocorticoids act at glucocorticoid receptor sites in corticolimbic structures, such as the hippocampus, to regulate HPA activity (Figure 4). Such feedback effects commonly inhibit hypothalamic CRF expression. The high-LG offspring showed significantly increased hippocampal glucocorticoid receptor expression, enhanced glucocorticoid negative-feedback sensitivity, and decreased hypothalamic CRF levels. Indeed, the magnitude of the glucocorticoid response to acute stress was significantly correlated with the frequency of pup LG during the 1st week of life, as was the level of both hippocampal glucocorticoid receptor and hypothalamic CRF expression (all *r*s > .70; Liu et al., 1997). Importantly, pharmacological manipulations that block the effect of the glucocorticoid receptor eliminate the maternal effect on the HPA response to stress, suggesting that the differences in hippocampal glucocorticoid receptor expression are directly related to those at the level of HPA function.

Pup LG is a major source of tactile stimulation for the neonate. Experimental models that directly apply tactile stimulation, through the stroking of the pup with a brush, provide direct evidence for the importance of tactile stimulation derived from pup LG. Thus, stroking pups over the 1st week of life increases hippocampal glucocorticoid receptor expression (Jutapakdeegul, Casalotti, Govitrapong, & Kotchabhakdi, 2003) and dampens behavioral and HPA responses to stress (Burton et al., 2007; Gonzalez, Lovic, Ward, Wainwright, & Fleming, 2001). Likewise, manipulations of lactating mothers that directly increase the frequency of pup LG also increase hippocampal glucocorticoid receptor expression and decrease HPA responses to stress (Francis et al., 1999; Toki et al., 2007).

The offspring of the high- and low-LG mothers also differed in behavioral responses to stress (Caldji et al., 1998; Caldji et al., 2003; Francis et al., 1999). As adults, the offspring of the high-LG mothers showed decreased startle responses, substantially less fearfulness in the presence of stressors, such as novel environments. Moreover, active defensive responses, such the burying of threatening stimuli, are more conspicuous among the adult offspring of low-LG mothers (Menard et al., 2004). While such pervasive effects are no doubt associated with alterations in multiple neural systems, there are robust effects of maternal care on the central CRF systems, including those that lie outside of the hypothalamus. The activation of fear behavior corresponds to an increase in CRF release from the amygdala and bed nucleus of the stria terminalis onto catecholaminergic cell bodies in the locus coeruleus. CRF acts at CRF$_1$ receptors in the locus coeruleus to stimulate the release of norepinephrine in a variety of corticolimbic structures (Bale & Vale, 2004; Valentino, Curtis, Page, Pavcovich, & Florin-Lechner, 1998). Gamma-aminobutyric acid type A (GABA), which is the primary source of neural inhibition in the adult mammalian brain, dampens the activation of this CRF–catecholamine connection during stress. The offspring of the high-LG mothers show decreased CRF$_1$ receptor levels in the locus coeruleus and increased GABA$_A$/benzodiazepine receptor levels in the basolateral and central nucleus of the amygdala, as well as in the locus coeruleus and decreased CRF expression in the amygdala (Caldji et al., 1998; Caldji et al., 2003). The adult offspring of high-LG mothers are more sensitive to the inhibitory effects of benzodiazepines on fear behavior (Fries, Moragues, Caldji, Hellhammer, & Meaney, 2004). Receptors for the benzodiazepines (e.g., diazepam) are part of the GABA$_A$ receptor complex, and the anxiolytic effects of these compounds occur through an ability to enhance the effect of GABA at the GABA$_A$ receptor site. GABA$_A$, or benzodiazepine receptor agonists, suppress CRF expression in the amygdala, thus reducing activity within the amygdala–locus coeruleus and decreasing norepinephrine responses to stress. Predictably, stress-induced increases in norepinephrine that are normally stimulated by CRF are significantly higher in the offspring of the low-LG offspring. The increased release of norepinephrine is consistent with the enhanced fearfulness of these animals. Thus, increased pup LG is associated with the enhanced efficacy of systems that normally serve to inhibit the expression and actions of CRF. These systems include the hippocampal glucocorticoid receptor and the GABA$_A$ receptor in the amygdala. Both effects involve sustained alterations in gene expression as a function of maternal care.

The complexity of such maternal effects on gene expression is apparent in the alterations in GABA$_A$ receptor function. The GABA$_A$ receptor is a multiprotein complex that comprised five individual subunits, each of which is a product of a distinct genomic region. An interesting feature to this system is that there are at least 19 different subunits that can be employed in the formation of a GABA$_A$ receptor. The activity of the receptor is determined by its subunit composition. For example, the inclusion of an a$_1$ subunit confers an increased affinity of the receptor for GABA, enhancing GABAergic activity at the GABA$_A$ receptor. Others, such as the g$_2$ subunit, will define the presence of a benzodiazepine binding site that further increases the inhibitory function of the GABA$_A$ receptor. The adult offspring of high-LG mothers show significantly increased expression of both the a$_1$ and g$_2$ subunits. The effect is almost unique to the amygdala and is reversed with cross-fostering (Caldji et al., 2003).

The results of these studies suggest that the behavior of the mother toward her offspring can "program" stable changes in gene expression that then serve as the basis for individual differences in behavioral and neuroendocrine responses to stress in adulthood. The maternal effects on phenotype are associated with sustained changes in the expression of genes in brain regions that mediate responses to stress, and form the basis for stable individual differences in stress reactivity. These findings provide a potential mechanism for the influence of parental care on vulnerability/resistance to stress-induced illness over the lifespan. However appealing, this hypothesis has yet to be directly confirmed. But the critical issue for this article is simply that of *how* maternal care might stably affect gene expression. How are variations in the social interactions between the mother and her offspring "biologically embedded" so as to stably alter the activity of specific regions of the genome? The answers to these questions appear to involve the ability of social interactions in early development to actually modify the structure of the relevant genomic regions.

Epigenetic Regulation of the Genome

When we think of genomic influences we most commonly imagine effects associated with variation in nucleotide sequence—the genetic code. Yet, this is only one form of information contained on the DNA. Despite the reverence afforded DNA, a gene is basically like any other molecule in the cell; it is subject to physical modifications. These modifications alter the structure and chemical properties of the DNA, and thus gene expression. Collectively, the modifications to the DNA and its chromatin environment can be considered as an additional layer of information that is contained within the genome. This information is thus *epigenetic* in nature (the name derives from the Greek *epi* meaning "upon" and *genetics*). The acetylation of the histone proteins referred to earlier is one example of an epigenetic modification. Epigenetic modifications do not alter the sequence composition of the genome. Instead, epigenetic marks on the DNA and the other features of the chromatin regulate the operation of the genome. Thus, *epigenetics* has been defined as a functional modification to the DNA that does not involve an alteration of sequence. While this definition has recently been subjected to revision (Bird, 2007; Hake & Allis, 2006), the essential features of epigenetic mechanisms are (a) structural modifications to chromatin either at the level of the histone proteins (Figure 2) or the DNA, (b) regulation of the structure and function of chromatin, (c) affects on gene expression, and (d) that these effects occur in the absence of any change in nucleotide sequence. The functional byproduct of the epigenetic modifications is that of a change in gene transcription.

The classic epigenetic alteration is that of DNA methylation, which involves the addition of a methyl group onto cytosines in the DNA (Bird, 1986; Holliday, 1989; Razin & Cedar, 1993; Razin & Riggs, 1980). The methylation of DNA is an active biochemical modification that in mammals selectively targets cytosines and is achieved through the actions of a class of enzymes, DNA methyltransferases, which transfer the methyl groups from methyl donors. There are two critical features to DNA methylation: First, it is a stable chemical modification, and second, it is associated with the silencing of gene transcription (Bestor, 1998; Bird, 2002; Bird & Wolffe, 1999; Razin, 1998).

Until recently, DNA methylation patterns on the genome were thought to be overlaid upon the genome only during early periods in embryonic development. This belief was derived in part from the experimental models commonly used to study DNA methylation. DNA methylation-induced gene silencing mediates two of the most commonly studied examples of epigenetic silencing, namely, X-chromosome inactivation and gene imprinting. Mammalian females bear two copies of the X-chromosome. The inactivation of one copy of the X-chromosome occurs in all mammalian females and is essential for normal function (i.e., maintaining a constant gene dosage in males and females). The silencing of the X-chromosome is associated with DNA methylation (Mohandas, Sparkes, & Shapiro, 1981; Riggs & Pfeifer, 1992; see Hellman & Chess, 2007, for a more current update). The second example of epigenetic-mediated gene silencing is that of gene imprinting (da Rocha & Ferguson-Smith, 2004; Reik, 2001), a remarkable subject in its own right, and one with considerable implications for growth and development (Charalambous, da Rocha, & Ferguson-Smith, 2007). For humans and other mammals, the expression-specific genes are determined by the parent of origin. For certain genes, the copy derived from the mother is active, while that emanating from the father is silenced—a ''maternally imprinted gene.'' In other cases, it is the reverse; the copy of the gene inherited from the father that is active, while that from the mother is silenced—a ''paternally imprinted gene.'' The silent copy is methylated in DNA regions that regulate gene expression and thus inactive. Again, the epigenetic marks associated with gene imprinting are established very early in life. These marks, as well as those associated with X-chromosome inactivation, are stable, leaving researchers in the field with the impression that under normal conditions DNA methylation occurs early in embryonic life and is largely irreversible. Indeed, it was commonly thought that DNA methylation was an actively dynamic process only during periods of cell division such that in mature, postmitotic cells further alteration of methylation patterns was improbable. Moreover, the loss of cytosine methylation in such models is associated with profound pathology. This perspective was further reinforced by findings showing that an alteration of DNA methylation at critical genomic targets (i.e., tumor suppressors) is associated with cancer (Eden, Gaudet, Waghmare, & Jaenisch, 2003; Feinberg, 2007; Laird, 2005).

While these assumptions concerning DNA methylation appear valid for the examples cited earlier, recent studies reveal that DNA methylation patterns are actively modified in mature (i.e., fully differentiated) cells, including, and perhaps especially, neurons and that such modifications can occur in animals in response to cellular signals driven by environmental events (Bird, 2007; Jirtle & Skinner, 2007; Meaney & Szyf, 2005). For example, variations in the diet of mice during gestation or later in development, such as the early postweaning period, can stably alter the methylation status of the DNA (Cooney, Dave, & Wolff, 2002; Waterland & Jirtle, 2003; Waterland, Lin, Smith, & Jirtle, 2006; Whitelaw & Whitelaw, 2006). Likewise, both mature lymphocytes (Bruniquel & Schwartz, 2003; Murayama et al., 2006) and neurons (e.g., Champagne, 2008; Champagne et al., 2006; Lubin, Roth, & Sweatt, 2008; Martinowich et al., 2003; Sweatt, 2009) show changes in the DNA methylation patterns at critical genomic regions in response to environmental stimuli that stably alter cellular function. The ability of environmental signals to actively remodel epigenetic marks that regulate gene expression is a rather radical change in our understanding of the environmental regulation of gene expression. Such epigenetic modifications are thus a candidate mechanism for the environmental ''programming'' of gene expression.

DNA Methylation and Gene Transcription

DNA methylation is associated with the silencing of gene transcription. This effect appears to be mediated in one of two ways (Bird, 2002). First, wide swaths of DNA can be methylated and the shear density of methylation precludes transcription factor binding to DNA sites, thus silencing gene expression. The second manner is subtler, and probably far more prevalent, in regions with more dynamic variations in gene transcription, such as the brain. In this case, selected cytosines are methylated and the presence of the methyl group attracts a class of proteins know as methylated-DNA binding proteins (Klose & Bird, 2006). These proteins, in turn, attract an entire cluster of proteins, known as the repressor complexes that are the active mediators of the gene silencing. The HDACs are a critical component of the repressor complex. HDACs prevent histone acetylation and favor a closed chromatin state that constrains transcription factor binding and gene expression (Figure 2 and see earlier). Compounds that inhibit HDACs can thus increase transcription from methylated DNA.

Epigenetics and the Social Environment

The following section describes studies of the molecular basis for the effects of maternal care on the development of individual differences in gene expression and stress responses. The mechanism for this interaction is epigenetic, involving alterations in DNA methylation at specific sites in the genome. In summary, variations in mother–infant interactions in the rat alter the extra- and intracellular environment of neurons in selected brain regions. Such alterations directly modify the epigenetic marks on regions of the DNA that regulate the transcription of the glucocorticoid receptor, which in turns regulates the HPA response to stress. These epigenetic marks are stable, enduring well beyond the period of maternal care, and thus provide a molecular basis for a stable maternal effect on the phenotype of the offspring. Thus, the behavior of the mother directly alters cellular signals that then actively sculpt the epigenetic landscape of the offspring, influencing the activity of specific regions of the genome and the phenotype of the offspring.

Epigenetic Effects of Variations in Maternal Care

The critical feature of the maternal effects described earlier is that of persistence. The differences in the frequency of pup LG between high- and low-LG mothers are limited to the 1st week of postnatal life. And yet the differences in gene expression and neural function are apparent in adulthood. How might the effects of an essentially social interaction stably alter the expression of the glucocorticoid receptor gene?

The focus of the epigenetic studies is the NGFI-A consensus sequence in the exon 1_7 promoter (Figure 1) that activates glucocorticoid receptor expression in hippocampal neurons. The tactile stimulation associated with pup LG increases 5-HT metabolism in the hippocampus. As described earlier (Figure 3), in vitro studies show that 5-HT acts on 5-HT$_7$ receptors to initiate a series of intracellular signals that culminate with an increase in the expression of NGFI-A as well as in the CREB-binding protein. Comparable effects occur in vivo. Manipulations that increase pup LG by lactating rats result in an increased level of cAMP as well as NGFI-A (Meaney et al., 2000). Pups reared by high-LG mothers show increased NGFI-A expression in hippocampal neurons as well as an increased binding of NGFI-A to the exon 1_7 promoter sequence (Hellstrom , Zhang, Diorio, & Meany, 2009; Weaver et al., 2007). Moreover, the binding of NGFI-A to the exon 1_7 promoter sequence is actively regulated by mother–pup interactions, such that there is increased NGFI-A bound to the exon 1_7 promoter immediately following a nursing bout but not at a period that follows 25 min without mother–pup contact (Hellstrom et al., 2009).

Nerve growth factor-inducible factor A and the CREB-binding protein form a complex that binds directly to the exon 1_7 promoter sequence and actively redesigns the methylation pattern at this region of the genome (Weaver et al., 2004; Weaver et al., 2007). Thus, as adults the offspring reared by high-LG mothers show very modest levels of methylation at the 5′-CpG of the NGFI-A consensus sequence (Figure 5). This effect on methylation is very precise. Lying only a few nucleotides removed from this site is 3′-CpG site (Figure 5), the methylation status of which is unaffected by maternal care.

A rather novel aspect to the effect of maternal care on DNA methylation was apparent in the results of a simple developmental study examining the methylation status of the 5′- and 3′-CpG sites from late in fetal life to adulthood (Weaver et al., 2004). Neither the 5′- nor the 3′-CpG site is methylated in hippocampal neurons from fetal rats, whereas both sites are heavily methylated on the day following birth, with no difference as a function of maternal care. These findings reflect what is

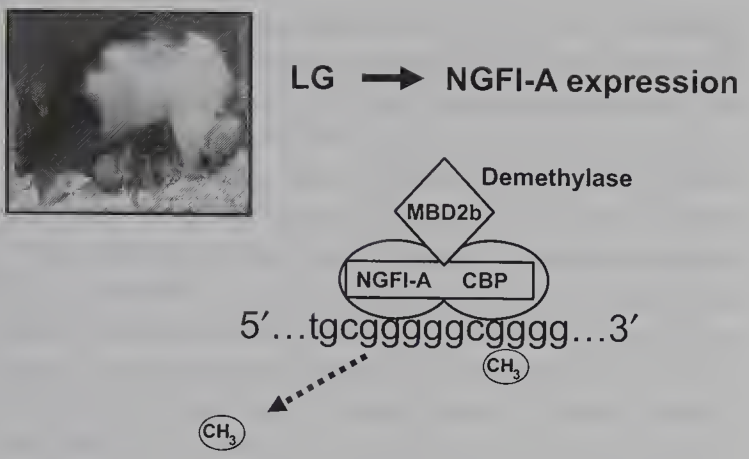

Figure 5. A working hypothesis for the experience (maternal care) driven remodeling of the epigenetic state of the NGFI-A consensus binding sequence over the 1st week of postnatal life in the offspring of high-LG mothers.
Note. The binding of a NGFI-A/CBP complex actively targets the association of a putative demethylase (MBD2) resulting in the removal of the methyl group from the 5′-CpG site of the NGFI-A binding site (Meaney & Szyf, 2005). CBP = CREB-binding protein; LG = licking/grooming; NGFI-A = nerve growth factor-inducible factor A.

referred to as *de novo methylation*, whereby a methyl group is applied to previously unmethylated sites. However, between the day following birth and the end of the 1st week of life, the 5′-CpG is "demethylated" in pups reared by high-, but not low-LG mothers. The difference then persists into adulthood. Importantly, the period over which the demethylation occurs is precisely that during which high- and low-LG mothers differ in the frequency of pup LG; the difference in pup LG between high- and low-LG mothers is not apparent in the 2nd week of postnatal life (Caldji et al., 1998; Champagne, Francis, et al., 2003).

The demethylation of the 5′-CpG site occurs as a function of the same 5-HT-activated signals that regulate glucocorticoid receptor gene expression in cultured hippocampal neurons (Weaver et al., 2007). Thus, when hippocampal neurons of embryonic origin are placed in culture and treated with 5-HT, which mimics the extracellular signal associated with maternal LG, the 5′-CpG site is demethylated; there is no effect at the 3′-CpG site. The binding of NGFI-A to the exon 1_7 site is critical. Hippocampal neurons that are rendered incapable of increasing NGFI-A expression through antisense or siRNA treatment show neither the demethylation of the 5′-CpG site nor the increase in glucocorticoid receptor expression (Weaver et al., 2007). Likewise, a mutation of the NGFI-A site that completely abolishes the binding of NGFI-A to the exon 1_7 promoter also prevents the demethylation of the 5′-CpG. Finally, the infection of hippocampal neurons with a virus containing a construct that was engineered to express high levels of NGFI-A produces demethylation of the 5′-CpG of the exon 1_7 promoter sequence and increased glucocorticoid receptor expression.

But there is a complication. If DNA methylation blocks transcription factor binding and the 5′-CpG site of the exon 1_7 promoter is heavily methylated in neonates, then how might maternally activated NGFI-A bind to and remodel the exon 1_7 region? And why is the effect apparent at the 5′- but not the 3′-CpG? The answer to these questions appears to involve other transcriptional signals that are affected by maternal care. Levels of the transcription factor specific protein-1 (SP-1) and the CREB-binding protein are also increased in the hippocampus of pups reared by high-LG mothers (Hellstrom et al., 2009; Weaver et al., 2007). The exon 1_7 promoter contains a DNA sequence that binds SP-1 and this region overlaps with that for NGFI-A. SP-1 can actively target both methylation and demethylation of CpG sites (Brandeis et al., 1994). The 5′-CpG site is the region of overlap in the binding sites. The CREB-binding protein, on the other hand, acts as a histone acetyltransferase, an enzyme capable of acetylating histone tails, including the exon 1_7 region, opening chromatin and permitting the binding of transcription factors such as NGFI-A and SP-1. Increasing histone acetylation can lead to transcription factor binding at previously methylated sites, and the subsequent demethylation of these regions (Szyf, Weaver, Champagne, Diorio, & Meaney, 2005).

The NGFI-A transcription factor binds to multiple sites across the genome. If NGFI-A-related complexes target demethylation, then one might assume that other NGFI-A-sensitive regions should show a maternal effect comparable to that observed with the glucocorticoid receptor. Zhang, Hellstrom, Wei, and Meaney (2009) showed that the hippocampal expression of the *GAD1* gene that encodes for glutamic acid decarboxylase, a rate limiting enzyme in the production of GABA, is increased in the adult offspring of high-LG mothers. This effect is associated with increased cytosine methylation of an NGFI-A response element. Moreover, as with the effect on the glucocorticoid receptor, an in vitro increase in NGFI-A expression mimics the effects of increased pup LG.

In summary, the maternally induced changes in specific intracellular signals in hippocampal neurons can physically remodel the genome. The increased binding of NGFI-A that derives from pup LG appears critical for the demethylation of the exon 1_7

promoter. We suggest that this process involves accompanying increases in SP-1 and the CREB-binding protein, and that the combination of these factors results in the active demethylation of the exon 1_7 promoter. It should be noted that there are important features of this model that remain to be clearly defined, including the identification of the enzyme that is directly responsible for the demethylation. Nevertheless, the events described to date represent a model by which the biological pathways activated by a social event may become imprinted onto the genome. This imprint is then physically apparent in the adult genome, resulting in stable alterations (or programming) of gene expression.

The Functional Importance of the Social Imprint

The presence of a methyl group on the 5′-CpG of the NGFI-A binding site is functionally related to glucocorticoid receptor gene expression in adult animals. In vitro studies reveal that the methylation of the 5′-CpG site reduces the ability of NGFI-A to bind to the exon 1_7 promoter and activate glucocorticoid receptor transcription (Weaver et al., 2007). These findings are consistent with the model described earlier, whereby DNA methylation impedes transcription factor binding and thus the activation of gene expression. The question concerns the in vivo situation. In contrast to the situation with neonates, there is no difference in NGFI-A expression as a function of maternal care among adult animals. However, the altered methylation of the exon 1_7 promoter would suggest differences in the access of NGFI-A to its binding site on the promoter. Chromatin-immunoprecipitation assays, which permit measurement of the direct interaction between a specific protein and a defined region of the DNA, reveal increased NGFI-A association with the exon 1_7 promoter in hippocampi from adult offspring of high- compared to low-LG mothers (Weaver et al., 2004; Weaver et al., 2005). These findings show that in the living animal, under normal conditions, there is more NGFI-A associated with the exon 1_7 promoter in hippocampal neurons of adult animals reared by high- compared with low-LG mothers.

There is also evidence that directly links the maternal effect on the epigenetic state of the exon 1_7 promoter to the changes in glucocorticoid receptor expression and thus HPA responses to stress. Recall that the methylation of specific CpG sites can diminish transcription factor binding through the recruitment of repressor complexes that include HDACs. The HDACs deactylate histone tails, thus favoring a closed chromatin configuration. Indeed, the exon 1_7 promoter is more prominently acetylated in hippocampi from adult offspring of high- compared with low-LG mothers (Weaver et al., 2004, 2005). This finding is consistent with the increased transcription of the glucocorticoid receptor gene in animals reared by high- versus low-LG mothers. A subsequent study (Weaver et al., 2004) examined the effects of directly blocking the actions of the HDACs in the adult offspring of high- and low-LG mothers. An HDAC inhibitor was infused directly into the hippocampus daily for 4 consecutive days. The treatment with the HDAC inhibitor produces a series of predictable results that reflect a cause–effect relation between DNA methylation and gene expression. First, HDAC blockade eliminates the differences in the acetylation of the histone tails of the exon 1_7 promoter in hippocampal samples from high- and low-LG mothers. Second, the increased histone acetylation of the exon 1_7 promoter in the offspring of low-LG mothers is associated with an increase in the binding of NGFI-A to the exon 1_7 promoter in the offspring of low-LG mothers, eliminating the maternal effect on NGFI-A binding to the exon 1_7 promoter. Comparable levels of NGFI-A binding to the exon 1_7 promoter then eliminate the maternal effect on hippocampal glucocorticoid receptor expression, such that glucocorticoid receptor levels in the adult offspring of low-LG mothers treated with the HDAC inhibitor are comparable to those in animals reared by high-LG mothers. And most importantly, the infusion of the HDAC inhibitor reversed the differences in the HPA response to stress.

Histone deacetylase inhibition increases NGFI-A binding to the exon 1_7 promoter in the offspring of low-LG mothers. The studies with neonates reveal that increased NGFI-A binding results in the demethylation of the 5′-CpG. In vitro, the introduction of a viral tool that leads to the increased expression of NGFI-A is sufficient to demethylate the exon 1_7 promoter. We (Weaver et al., 2007) argue that the binding of NGFI-A is critical for the demethylation of the 5′-CpG site. The same effect is apparent in vivo and even with the adult animals used in the studies described earlier. HDAC infusion into the hippocampus increases NGFI-A binding to the exon 1_7 promoter in the adult offspring of low-LG mothers and decreases the level of methylation of the 5′-CpG site on the exon 1_7 promoter. A subsequent study (Weaver et al., 2005) showed that the reverse pattern of results could be obtained in response to a dietary manipulation (methionine):

Greater methylation of the 5′-CpG in the offspring of high-LG mothers decreased NGFI-A binding and GR expression and increased HPA responses to stress (Weaver et al., 2005).

While these studies employ rather crude pharmacological manipulations, the results are critical as they suggest that fully mature neurons in an adult animal express the necessary enzymatic machinery to demethylate or remethylate DNA. Thus, it is possible that environmentally driven changes in neuronal transcriptional signals could potentially remodel the methylation state of specific regions of the DNA (Meaney & Szyf, 2005). The cytosine methylation state of a promoter for the brain-derived neurotrophic factor (*bdnf*) gene is also influenced by maternal care in early life (Roth, Lubin, Funk, & Sweatt, 2009). Indeed, Lubin et al. (2008) provided evidence for an alteration of the methylation state of the same *bdnf* promoter following contextual fear conditioning in adult rats (also see Bredy et al., 2007). These effects are consistent with previous reports of activity-dependent alterations in the methylation of the same *bdnf* promoter (Martinowich et al., 2003) and suggest that epigenetic states might be altered by a wide range of biologically relevant events that result in synaptic remodeling (Meaney & Szyf, 2005; Renthal & Nestler, 2008; Sweatt, 2009). Such epigenetic modifications might therefore underlie a wide range of stable changes in neural function following exposure to highly salient events (e.g., chronic stress, drugs of abuse, reproductive phases such as parenting, etc.), and are thus logical mechanisms for environmentally induced alterations in mental health (Akbarian & Huang, 2009; Jiang et al., 2008; Tsankova, Renthal, Kumar, & Nestler, 2007). While such effects have yet to be reported for DNA methylation, modifications of histone proteins are associated with exposure to drugs of abuse and stressors in rodent models (Renthal & Nestler, 2008; Renthal et al., 2007).

A set of recent studies (McGowan et al., 2009) suggests that comparable epigenetic modifications might occur in humans in response to variations in parent–offspring interactions. DNA was extracted from hippocampal samples obtained from victims of suicide or from individuals that had died suddenly from other causes (auto accidents, heart attacks, etc.). The samples were obtained from the Québec Suicide Brain Bank, which conducts forensic phenotyping that includes a validated assessment of psychiatric status and developmental history (e.g., McGirr, Renaud, Seguin, Alda, & Turecki, 2008). The studies examined the methylation status of the exon 1_F promoter of the glucocorticoid receptor, which corresponds to the exon 1_7 promoter in the rat (Turner & Muller, 2005). The results showed increased DNA methylation of the exon 1_F promoter in hippocampal samples from suicide victims compared with controls, but only if suicide was accompanied with a developmental history of child maltreatment. Child maltreatment, independent of psychiatric state, predicted the DNA methylation status of the exon 1_F promoter. As in the previous rodent studies, the methylation state of the exon 1_F promoter also determined the ability of NGFI-A to bind to the promoter and activate gene transcription. While such studies are obviously correlational, and limited by postmortem approaches, the results are nevertheless consistent with the hypothesis that variations in parental care can modify the epigenetic state of selected sites of the human genome. Moreover, the findings are also consistent with studies that link childhood abuse to individual differences in stress responses (Heim et al., 2000). Childhood abuse was associated with an increase in pituitary ACTH responses to stress among individuals with or without concurrent major depression. Heim et al.'s (2000) findings are particularly relevant since pituitary ACTH directly reflects central activation of the HPA stress response and hippocampal GR activation dampens HPA activity. These findings are consistent the rodent studies cited earlier investigating epigenetic regulation of the glucocorticoid receptor gene and with the hypothesis that early life events can alter the epigenetic state of relevant genomic regions, the expression of which may contribute to individual differences in the risk for psychopathology (Holsboer, 2000; Neigh & Nemeroff, 2006; Schatzberg, Rothschild, Langlais, Bird, & Cole, 1985).

Transgenerational Effects

Individual differences in stress responses in the adult rat are associated with naturally occurring variations in maternal care during infancy. Manipulations that alter mother–pup interactions in the rat alter patterns of gene expression and stress response in the offspring (e.g., Francis et al., 1999; Meaney, 2001; Roth et al., 2009; Toki et al., 2007). Such effects are certainly familiar to child psychologists working with parenting training programs. Moreover, these maternal effects might also serve as a possible nongenomic mechanism by which selected traits could be transmitted from one generation to another through variations in mother–pup interactions. Interestingly, low-LG mothers are more fearful than are high-LG dams (Francis, Champagne, & Meaney, 2000). Individual differences in stress reactivity are apparently transmitted across generations: Fearful mothers beget more stress reactive offspring. The obvious question is whether the transmission of these traits occurs only as a function of genomic-based inheritance. If this is the case, then the differences in maternal behavior may be simply be an epiphenomenon and not causally related to the development of individual differences in stress responses. The issue is not one of inheritance but rather the mode of inheritance. However, the results of the previously cited cross-fostering studies indicate that individual differences at the level of gene expression or complex phenotype can be directly altered during the postnatal period by maternal behavior. This interpretation is buttressed from studies showing that tactile stimulation of pups by the experimenter with a brush, so-called stroking, increases hippocampal NGFI-A (Hellstrom et al., 2009) increases hippocampal GR expression (Jutapakdeegul et al., 2003), and dampens HPA responses to stress in adulthood (Burton et al., 2007; Gonzalez et al., 2001).

The cross-fostering studies also reveal that individual differences in maternal behavior are transmitted from mother to the female offspring. Hence, as adults, the female offspring of more fearful, low-LG mothers are also more fearful low-LG mothers (Francis et al., 1999; also see Fleming, O'Day, & Kraemer, 1999). Regardless of their biological origins, females that are reared by high-LG mothers are less fearful and show an increased frequency of pup LG. And the mechanism for the intergenerational transmission of such individual differences appears to be the difference in the frequency of pup LG during early postnatal life. Fleming and colleagues found that as adults, females rats deprived of maternal showed reduced frequencies of multiple forms of maternal behavior, and such effects were reversed if animals were provided with tactile stimulation by stroking the pups with a brush over the first weeks of life (Gonzalez et al., 2001; Lovic, Gonzalez, & Fleming, 2001; Melo et al., 2006). Moreover, the stroking in infancy also increased the expression of maternal behaviors in response to ovarian hormones in adulthood (Novakov & Fleming, 2005), an effect that is comparable to that associated with increased pup LG (Champagne, Diorio, Sharma, & Meaney, 2001; see also next).

The individual differences in pup LG involve differences in estrogen receptor α-gene expression in the medial preoptic area (MPOA) of the hypothalamus, a region that is critical for maternal behavior in the rat (Fleming et al., 1999; Numan & Insel, 2003). There is increased estrogen receptor a expression in female offspring of high-LG mothers (Champagne, Weaver, Diorio, Sharma, & Meaney, 2003). Estrogen acts during late gestation to increase oxytocin receptor levels in the MPOA (Fahrbach & Pfaff, 1986; Pedersen, 1997), and this effect is greater in the female offspring of high- compared to low-LG mothers (Champagne et al., 2001), reflecting the increased sensitivity to estrogen. Oxytocin appears to act at oxytocin receptor levels in the MPOA to facilitate the release of dopamine from neurons in the ventral tegmental nucleus, and the increased dopamine release then activates pup LG in lactating female rats (Champagne, Stevenson, Gratton, & Meaney, 2004; Shahrohk et al., in press). This effect is abolished with the infusion of an oxytocin receptor antagonist into the ventral tegmental area (Shahrohk et al., in press). Likewise, the same oxytocin receptor antagonist completely eliminates the differences in maternal behavior between high- and low-LG mothers (Champagne et al., 2001). Drugs that block the reuptake of synaptic dopamine, thus increasing the overall dopaminergic signal, increase pup LG in low-LG mothers and eliminate the difference in maternal behavior between high- and low-LG mothers. In summary, the increased estrogen receptor a expression in the MPOA of high-LG mothers leads to greater sensitivity to estrogen, an increased level of oxytocin levels in MPOA neurons that project directly to the dopamine neurons in the ventral tegemental regions, and greater activation of dopamine release during nursing bouts. And the differences in estrogen receptor a expression, like those in pup LG, are reversed with cross-fostering (Champagne, Francis, et al., 2003), suggesting that maternal care regulates the activity of the estrogen receptor in the MPOA, which then forms the basis for subsequent "inherited" differences in maternal behavior.

This finding reveals another example of a maternal effect on gene expression, and there is evidence for epigenetic mediation. The activation of the estrogen receptor α-gene in the rat brain occurs through the estrogen receptor 1B promoter. This promoter contains multiple cytosine sites that are potential targets for DNA methylation. Champagne et al. (2006) found increased cytosine methylation across the exon 1B promoter in the offspring of low-LG mothers. Activation of the exon 1B promoter occurs in response to the binding of the transcription factor Stat5, and the adult offspring of low-LG mothers show decreased Stat5 association with the exon 1B promoter in the MPOA. These findings suggest that differences in DNA methylation may mediate the effect of maternal care on the expression of estrogen receptor α in the MPOA and thus serve as the molecular basis for the nongenomic transmission of individual differences in maternal behavior from the mother to her female offspring.

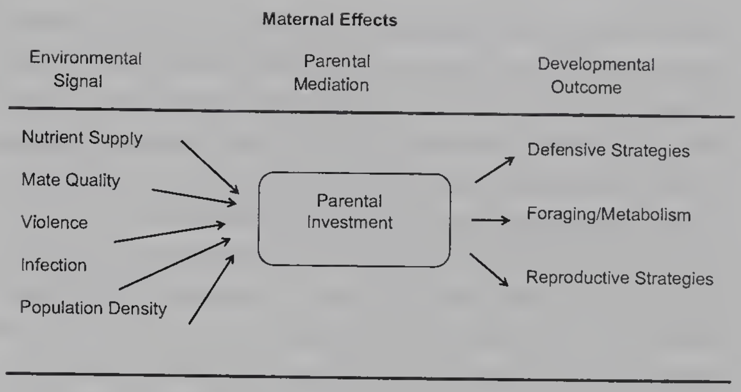

Figure 6. Summary of the literature from evolutionary biology on "maternal effects."

Note. The consistent theme reflected in these studies is that various environmental signals can alter multiple phenotypic outcomes through effects on parent–offspring interactions, broadly referred to as *parental investment*. The relevant form of the variation in parent–offspring interaction (investment) will vary depending upon the species. The principal idea is that of parental mediation and of coordinated effects on multiple phenotypic outcomes.

Adaptive Value of Epigenetic Maternal Effects

Variations in parental signals alter gene expression and thus the development of individual differences in complex phenotypes. But why bother? Why would nature configure such a process? Why transmit individual differences in stress reactivity or maternal behavior across generations through a process that is driven by parental care and mediated by the complex cellular machinery necessary to rearrange epigenetic markings on the DNA? Why not simply leave such issues of inheritance in the hands of classic genetic transmission? The answer may lie in the simple fact that unlike nucleotide sequence, epigenetic marks are dynamic and indeed reversible. The more flexible epigenetic mechanism would provide the basis for an adaptive parental effect: In the rat at least, parents can actively remodel epigenetic marks and thus affect patterns of gene expression in the offspring. Such effects do not occur at the level of nucleotide sequence.

Studies in the fields of evolutionary biology and ecology report maternal effects on phenotype in the offspring across a wide range of species (see Figure 6; Badyaev, 2008; Cameron et al., 2005; Meaney, 2007; Mousseau & Fox, 1998; Rossiter, 1998). Despite the fact that these studies have been performed largely with simpler organisms, such as plants, insects, and reptiles, the emerging theme is much the same as that described earlier in studies with human families: Environmental adversity decreases parental investment in the offspring and thus alters phenotypic development. And there is evidence that these phenotypic effects are adaptive within adverse settings (Mousseau & Fox, 1998).

Obviously, the form of "parental investment" varies across species. In plants, the variation may involve seed quality. Among certain insects "investment" would include the nutrient value of the "propulgate," the food source left by the mother for the hatching offspring. While some insects do exercise postnatal behavioral care of the offspring, variations in this form of investment are most relevant for mammalian species. Nevertheless, the stability of the relation between the quality of the prevailing environment, parental investment, and phenotypic development in the offspring led Hinde (1986) to suggest that evolution may have actually shaped the offspring to "use" parental signals, such as variations in parental care behaviors, to forecast the quality of the environment in which they must function (also see Bateson, 1994; Bateson et al., 2004; Rossiter, 1998). Evolution should come to favor offspring that are able to accurately "read" variations in parental behavior as forecasts of environmental conditions and thus as useful signposts to guide developmental outcomes (Hinde, 1986). By definition, such responses should occur in reaction to variation within the normal range. Why evolve responses to forms of parental care that are unlikely to occur? Parents (or parent in some cases) are a logical source of such information since they are the one "environmentally informed" and constant experience for the offspring. Moreover, since parents are invested in the adaptive success of their biological offspring, one would expect that the fidelity of signals emanating from a parent would be greater than that of other adult conspecifics. Thus, to the extent that the parent and offspring share a common interest in the adaptive value of such phenotypic plasticity, selection may also act on the signaling capacity of the parent. Indeed, phenotypic plasticity in response to parental signals may also be thought of as a parental strategy, although it is clear that the benefits work in both directions as would be expected among organisms that share genes. In either case, the sensitivity of the offspring to parental signals during critical phases of development may be thought of as a strategy that favors a highly predictable relation between environmental conditions, parental input, and phenotypic variation in defensive responses. For the offspring, parents should matter.

Hinde's (1986) formulation implies an adaptive function for parental effects in preparing the offspring for the environmental demands that are likely to prevail during development and into adulthood (also see Bateson et al., 2004; Gluckman & Hanson, 2004; Meaney, 2001). Indeed, it is probably true that the environmental conditions of the adult are a reasonable predictor of those facing the offspring (with modern, urbanized human populations as a rare exception; Gluckman & Hanson, 2004; West & King, 1987). However, environmental conditions can vary with the migration of populations. Moreover, even within a similar environment, the ability of individuals to access resources can vary from one individual to another as a function of, for example, social dominance hierarchies. Success requires the ability to adapt, to fine-tune phenotypic development in relation to the prevailing environmental demands. Learning, of course, would provide a mechanism for such phenotypic plasticity. But learning requires trial and, unfortunately, error. Nature does not always permit such indulgences. Epigenetic variation may provide a mechanism for the dynamic regulation of the genomic machinery in response to variation in prevailing environmental conditions during development (Jablonka & Lamb, 2005). Such epigenetic adaptations could then occur directly as a result of the relevant environment condition (e.g., nutrient availability) or indirectly through parental mediation. Such effects could, for example, explain the enduring effects of childhood socioeconomic status on health outcomes in humans.

We suggest that parental signals over the perinatal period serve as an important catalyst for epigenetic remodeling of the genome. If such effects support an adaptive function, then there should be a high degree of fidelity between the quality of the environment and parental care. This argument rests upon at least three assumptions. First, there is a consistent relation between the quality of the environment and that of parental care. Second, variations in specific developmental outcomes should be adaptive. This includes an adaptive value to traits that appear to increase vulnerability to illness, such as increased stress reactivity. And third, the ecology of the neonate reliably predicts the conditions of adulthood.

Stress and Parenting

Perhaps, the most compelling evidence for a direct effect of environmental adversity on parent–offspring interactions emerges from the studies of Rosenblum, Coplan, and colleagues with nonhuman primates (Coplan, Andrews, Rosenblum, & Nemeroff, 1996). Bonnet macaque mother–infant dyads were maintained under typical lab conditions, with free, unhindered access to food (a low-foraging-demand condition) or one in which the amount of available food varied and required long periods of searching (high-foraging-demand condition). The high-foraging-demand condition severely disrupted mother–infant interactions, producing significant conflict. Infants of mothers housed under these conditions were more timid and fearful, with some revealing signs of depression that are commonly observed in maternally separated macaque infants. Such reactions were even apparent among infants that were in contact with their mothers. As adolescents, the infants reared in the high-foraging-demand conditions were more fearful, submissive, and showed less social play behavior. As expected, these conditions also affected the development of neural systems that mediate behavioral and endocrine response to stress. Adult monkeys reared under variable foraging demand (VFD) conditions showed increased central levels of CRF and increased noradrenergic responses to stress. It would be fascinating to see if such traits would then be transmitted to the next generation. In some rather remarkable cross-fostering studies, Maestripieri (2005) has shown that individual differences in maternal behavior are transmitted across generations in the rhesus monkey.

The critical issue here is that of a direct effect of environmental adversity on maternal behavior. Stress during pregnancy decreases maternal responsivity in lactating rats (Fride, Dan, Gavish, & Weinstock, 1985; Kinsley, Mann, & Bridges, 1998; Moore & Power, 1986). Gestational stress also eliminates the differences in pup LG between high- and low-LG mothers (Champagne & Meaney, 2006). Gestational stress decreases the frequency of maternal LG in the high-, but not in low-LG mothers (also see Smith, Seckl, Evans, Costall, & Smythe, 2004), and the effect is apparent even with subsequent litters in the absence of further exposure to stress. As expected, the effects on maternal behavior are apparent in the development of the offspring. As adults, the offspring of high-LG/gestationally stressed mothers were comparable to those of low-LG dams on measures of maternal behavior, as well as in fear behavior and hippocampal glucocorticoid receptor gene expression. These effects can be distinguished from those associated with prenatal stress in animals that were in utero during the imposition of the stressor by simply examining the offspring of subsequent litters in which the behavior of the mother remains affected, but in the absence of the stressor (Champagne & Meaney, 2006).

As mentioned earlier, there is considerable, albeit correlational, evidence for a relation between environmental adversity and parental care in humans. Environmental adversity influences emotional well-being in parents and these effects are reflected in alterations in parental care, commonly reflecting a decreased level of investment (Fleming, 1988; Repetti et al., 2002). Increased maternal stress is associated with less sensitive child care (Dix, 1991; Goldstein, Diener, & Mangelsdorf, 1996). The children of highly stressed primary caregivers tend to develop insecure parental attachment (Goldstein et al., 1996; Vaughn, Egeland, Sroufe, & Waters, 1979). Parents in conditions of poverty experience more negative emotions, irritability, depressed, and anxious moods, which lead to more punitive parenting (Belsky, 1993; Conger, McCarty, Yang, Lahey, & Kropp, 1984; Grolnick, Gurland, DeCourcey, & Jacob, 2002). The resulting patterns of parental behavior can affect the development of HPA responses to stress in the offspring (Heim et al., 2000; Pruessner, Champagne, Meaney, & Dagher, 2004), an effect that may associate with altered glucocorticoid receptor expression (McGowan et al., 2009). Hane and Fox (2006) found a direct relation between the quality of maternal care and behavioral inhibition in children. There is rather compelling evidence for parental mediation in the effects of impoverished environments on phenotypic development. Thus, the effects of poverty on emotional and cognitive development are, in part, mediated by variations in parent–offspring interactions. If parental care factors are statistically controlled, there no longer remains any discernible effect of poverty of child development (Conger, Ge, Elder, Lorenz, & Simons, 1994; McLoyd, 1998). Moreover, parents and parenting style are highly effective targets for intervention studies aimed at development outcomes in children living in adverse environmental conditions (Belsky, 1997; Fisher et al., 2000; Offord et al., 1992; Olds et al., 1998; Van den Boom, 1994).

Adaptive Value of Increased Stress Responses

Intergenerational transmission of individual differences in stress reactivity via parental behavior could represent an adaptive approach to development. Since the offspring usually inhabit a niche that is similar to their parents, the transmission of individual differences in traits from parent to offspring could serve to be adaptive with respect to survival. The conceptually challenging feature of this argument is that it requires that we identify an adaptive virtue to a phenotypic profile, such as increased HPA stress responses, that predict greater vulnerability to chronic illness.

Adverse environmental conditions such as those associated with poverty over the adult life of the parent have historically predicted more of the same for the offspring. The critical challenge over the course of development is to mold specific features of phenotype in a manner that is most appropriate to the level of environmental demand. This capacity for phenotypic plasticity (Agrawal, 2001; Mousseau & Fox, 1998) is a product of evolutionary forces. As such, it is critical to note that the ultimate measure of success for any phenotypic trait is the degree to which it enhances the probability for reproductive success. The health of the individual is a relevant consideration *only to the degree that it influences the ability to successfully reproduce.* Health will influence survival and the ability to attract mating opportunities, and may therefore be of relevance, at least during the period of active reproduction. However, the incidence of chronic illnesses that commonly occur in later life, once the prospects for reproductive activity have declined, is not a major consideration in evaluating the adaptive value of any specific trait in the evolutionary sense.

There is a very real divide between the way in which the success of development is evaluated by those working in the health sciences as compared to those in biology. Optimal development for those in the health sciences is judged by the quality of life and the absence of disease. For biologists, success is measured in the terms of the currency of natural selection—reproductive fitness. For biologists, there are no ideal phenotypes. Rather, the adaptive merits of phenotype are apparent only in relation to success within a particular set of environmental conditions: One single phenotype does not fit all. For example, an increase in the responsivity of an individual to threat (i.e., greater stress reactivity) is realistically considered as a risk factor for multiple forms of chronic illness. Thus, the catabolic effects associated with adrenal glucocorticoids or sympathetic catecholamines tend to be vilified, especially in psychology and psychiatry. Indeed, chronic elevations in the levels of these "stress mediators" can directly promote illness (Chrousos & Gold, 1992; Dallman et al., 2005; McEwen, 2007; Sapolsky et al., 2000; Walker, 2007). However, the bitter truth of adaptation and survival in the face adversity is that such hormonal stress responses are essential for continued life. The survival interests of an individual during periods of increased environmental demand are well served by behavioral (e.g., vigilance, fearfulness) and endocrine (HPA and metabolic/cardiovascular) responses to stress. These responses promote detection of potential threat, fear conditioning to stimuli associated with threat and avoidance learning. Moreover, the hormonal effectors of sympathoadrenal and HPA stress responses mobilize energy reserves through effects of lipolysis, glycolysis, and gluconeogenesis. These effects are the hallmark of the shift to catabolism that occurs during periods of stress and are essential for animals exposed to chronic stress, particularly if the stressor is coupled to conditions of famine. Indeed, the ability to survive sustained periods of nutrient deprivation depends upon the capacity to increase circulating levels of glucocorticoids and catecholamines. Impoverished environments are also commonly associated with multiple sources of infection. Under such conditions adrenal glucocorticoids serve as a potent defense against septic shock (Munck et al., 1984; Sapolsky et al., 2000). Among rats, animals with increased HPA responses to agents such as bacterial endotoxins are at reduced risk for sepsis. Interestingly, adults exposed to a bacterial endotoxin during the 1st week of life exhibit increased HPA responses to stress as well increased resistance to sepsis upon subsequent exposure to bacterial infection (Shanks, Larocque, & Meaney, 1995; Shanks et al., 2000). Conversely, postnatal conditions that increase maternal LG and dampen HPA responses to stress *increase* vulnerability to endotoxin-induced sepsis. These findings underscore the potentially adaptive value of increased HPA and sympathetic responses to stress, especially for individuals living under conditions of impoverishment and infection. Thus, the decreased parental investment associated with more stressful conditions may in fact be of benefit to the offspring, if indeed such conditions remain stable over time. Decreased parental investment might enhance the stress responses of the offspring, which could serve to protect against repeated periods of nutrient deprivation and infection. This theme is apparent in the effects of maternal care on neurocognitive development in the rat.

Maternal Care and Neurocognitive Development

Pup LG in the rat dynamically alters the activity of endocrine systems that favor of somatic growth (Levine, 1994; Schanberg et al., 1984). Comparable effects are apparent in the hippocampus, a brain region intimately associated with learning and memory. The neonatal offspring of high-LG mothers show increased hippocampal expression of genes that encode for neurotrophic factors, which supports the sprouting and survival of synapses, this effect includes the expression glutamate receptor subunits. The activation of glutamate receptors in the hippocampus stimulates synaptogenesis (Kirkwood, Dudek, Gold, Aizenman, & Bear, 1993; Schatz, 1990). Thus, as adults, the offspring of high-LG mothers show increased hippocampal synaptic density (Bredy, Humpartzoomian, Cain, & Meaney, 2003; Champagne et al., 2008; Liu et al., 2000) associated with more extensive dendritic arborization of both pyramidal and granule cell populations (Bagot et al., 2009; Champagne et al., 2008). The effect of maternal care on synaptic development suggests an increased capacity for synaptic plasticity in the offspring of high-LG mothers. Long-term potentiation (LTP) is an electrophysiological model of synaptic plasticity at specific neural sites that is thought to mimic the structural remodeling of synaptic connections that underlie learning and memory. Hippocampal LTP formation is indeed stronger in the adult offspring of High compared to Low LG mothers (Bagot et al., 2009; Bredy et al., 2003; Champagne et al., 2008). And not surprisingly, the adult offspring of high-LG mothers show improved performance hippocampal-dependent tests of learning and memory, such as spatial learning (Bredy, Zhang, Grant, Diorio, & Meaney, 2004; Liu et al., 2000) and object recognition (Bredy et al., 2004).

These findings suggest a rather predictable effect of maternal care on hippocampal development, involving enhanced synaptic development in neonatal life and an increased capacity for synaptic plasticity in adulthood, revealed in electrophysiological as well as behavioral studies. Such findings would seem to reflect an advantage for the offspring of high-LG mothers. But these findings fail to consider the issue of context. Studies of in vitro LTP are performed with hippocampal slices obtained from animals in the resting state. Studies of in vivo LTP or behavioral tests of learning and memory are performed in animals habituated to the testing conditions. What if animals were tested under more demanding, stressful conditions? Champagne et al. (2008) and Bagot et al. (2009)

examined LTP in hippocampal slices obtained from the adult offspring of high- or low-LG mothers under basal conditions, or in the presence of stress-like levels of glucocorticoids. Glucocorticoids are an endocrine signature of the stress response and known to diminish hippocampal LTP (Bodnoff et al., 1995; Diamond & Rose, 1994; Joels, Karst, Krugers, & Lucassen, 2007; Kim & Yoon, 1998; Shors, Foy, Levine, & Thompson, 1990). This effect is readily apparent in sections obtained from high-LG mothers. LTP under basal conditions is markedly greater in hippocampal slices from high- compared to low-LG offspring, and the magnitude of LTP in slices from high-LG offspring is markedly reduced by glucocorticoids. The exact *opposite* is observed in hippocampal slices prepared from the offspring of low-LG mothers: Glucocorticoids significantly enhance LTP to the levels observed in hippocampal slices from high-LG mothers under basal conditions. This is true for LTP obtained from multiple regions within the hippocampus (i.e., for aficionados of hippocampal anatomy, this included neurons within both the Ammon's Horn and the dentate gyrus). And an analogous effect is apparent at the level of learning and memory. When the adult offspring of high- and low-LG mothers are tested not under the benign conditions described earlier but in tests on contextual fear conditioning, the performance of the offspring of the low-LG mothers is significantly improved (i.e., increased learning of the context–shock contingency) over that of high-LG dams (Bagot et al., 2009; Champagne et al., 2008). Contextual fear conditioning is also a hippocampal-dependent test of learning and memory (Fanselow, 2000; Maren & Quirk, 2004), in this case one that involves the association of a context with an aversive event (i.e., a mild shock). Thus, both hippocampal synaptic plasticity and hippocampal-dependent learning and memory are enhanced in the offspring of low-LG mothers *under stressful conditions*. The effects of maternal care on hippocampal function are context dependent.

Implications

All cellular processes derive from a constant dialogue between the genome and environmental signals. Thus, genotype–phenotype relations are defined by the context within which the genome operates. Likewise, the consequences for Gene × Environment interactions at the level of function are defined by the broader context, including the demands of the prevailing environment. The results of studies on the effects of maternal care on hippocampal development in the rat reflect an important point. Although it is tempting to assume that increased pup LG enhances synaptic plasticity and cognitive performance, such effects are apparent only under conditions that are minimally stressful. Under stressful conditions, such as those typified by contextual fear conditioning, it is the offspring of low-LG mothers that show improved synaptic plasticity and learning. We suggest that such findings represent a situation in which parental care shapes adaptive phenotypes (Hinde, 1986; Meaney, 2001; Bateson et al., 2004; Zhang et al., 2004; Gluckman & Hanson, 2007). In the rat, environmental stressors decrease parental investment and enhance behavioral and endocrine responses to stress, as well as learning and memory under stressful conditions. If indeed the decreased parental investment accurately reflects an increased level of environmental demand for the offspring, then such effects could be highly adaptive. Regardless of the merits of this proposal, these findings attest to the simple fact that the adaptive value of any phenotypic profile depends upon the environmental context: There is no universally "ideal" phenotype.

There is also evidence for the potentially adaptive effects of increased stress reactivity that more directly bears on the interests of child and adolescent psychology. The research of Farrington, Gallagher, Morley, St Ledger, and West (1988) and Tremblay (e.g., Haapasap & Tremblay, 1994) on young males growing up in impoverished, high-crime urban settings illustrates the potential advantages of increased emotional stress reactivity. Both studies show that shy and more timid males are most successful in avoiding the pitfalls associated with "criminogenic" environments. Under such conditions, behavioral inhibition emerges as a protective factor (Haapasap & Tremblay, 1994), despite the fact that this same profile is associated with an increased risk for mood disorders in later life (Pérez-Edgar & Fox, 2005). Moreover, under such adverse conditions a parental rearing style that favored the development of a greater level of stress reactivity to threat could be viewed as adaptive. If indeed there is no single ideal phenotype, then it should follow *that there is no single ideal form of parenting*. If this conclusion has worth, then it leads us to question the wisdom of establishing parenting programs that foster parental skills based on studies of families rearing children under more favorable conditions.

Caveats

The magnitude and scope of the maternal effects on rodent development should not be surprising. Hinde (1986), Bateson (1994), and others have described the logic for the importance of maternal signals for the developing mammal. Indeed, even the gametes include parental signals apart from genomic DNA, such as RNAs and proteins, which influence embryonic development. Nevertheless, it is important to understand that the rodent studies described earlier are designed to examine how variations in maternal *can* affect development; they do not address the issue of *how* and to *what degree* maternal care influences development under normal circumstances in the rat. Thus, the model described earlier examines maternal effects on neural development in animals that are then housed under highly standardized conditions following the weaning period, eliminating the possibility that maternal effects might be subsequently altered by variations in the postweaning environment. Indeed, there is evidence that postweaning environments can reverse the effects of preweaning variations in maternal care in the rat (Bredy et al., 2003; Champagne et al., 2006). These studies are perhaps best considered as a model for the mechanisms by which social experience in early life can influence the structure and operation of the genome with respect to specific phenotypic outcomes. Indeed, as suggested by Belsky (1997), Rutter (2007), and others, the effects of environmental influences, such as maternal care, will vary across individuals, and the studies of Fox et al. (2005) in humans and Suomi and colleagues (Bennett et al., 2002; Champoux et al., 2002; Suomi, 2006) in the nonhuman primate, suggest that variation in genomic sequence may be a critical factor in determining sensitivity to parental signals.

The study of epigenetics provides a molecular mechanism for environmental effects of gene expression. But the ultimate effect on gene transcription is best thought of as an emergent property of the interaction between the epigenetic state and the underlying genome. Thus, genomic sequence determines the effects of epigenetic states on gene transcription. While DNA methylation is linked to transcriptional silencing, such relations are not universal and the strength of the relation may be determined by the underlying genomic sequence (Weber et al., 2007). For example, among promoters with a lower percentage of CpG dinucleotides, there appears to be a weaker relation between the overall level of methylation and that of gene transcription. Likewise, the presence of histone modifications (H3K4me) that associate with transcriptionally active genes appears to be determined not only by DNA methylation but also by the underlying genomic sequence. Such findings should dissuade us from assuming that genomic sequence is merely passive player in the definition of epigenetic states. The underlying genomic sequence influences the nature of potential epigenetic states as well as their importance for gene transcription. Finally, many transcriptionally inactive genes show relatively unmethylated promoters. While this finding does not preclude the possibility that specific modifications in the methylation status at critical CpG sites may define changes in gene transcription, such as occurs for the *IL2* gene (Murayama et al., 2006), it is important to bear in mind that DNA methylation is only one level of influence in the very complex biochemical machinery that regulates gene transcription. These are still early days in the study of the molecular mechanisms for the environmental programming of gene expression. But the door has clearly been opened.

General Conclusions

The effects of maternal care on gene expression and neural function in the rat provide an understanding of how environmental events, including variations in parent–offspring interactions at the level of behavior, can become physically imprinted upon the genome. Maternal care can directly alter intracellular signals that, in turn, structurally alter the DNA and its operation. These structural modifications involve DNA methylation, a classic epigenetic mark that regulates gene transcription. More recent studies suggest that comparable epigenetic modifications associate with learning and memory (Lubin et al., 2008; Miller & Sweatt, 2007), chronic exposure to drugs of abuse (Renthal & Nestler, 2008), and psychiatric illness (Grayson et al., 2005; Ptak & Petronis, 2008; Tsankova et al., 2007). The dynamic genome is probably a slightly foreign concept to those who imagine the DNA as simply the repository of the sequence information that forms what is commonly referred to as the "genetic code." But the research of the postgenomic era, with its focus on the operation rather than simply the composition of the genome, reveals that the DNA is an active target for remodeling by cellular signals that are activated by environmental events. The reality of the functional genome does not admit to main effects of either gene or environment, but rather to a constant interaction between the DNA and its environment.

The study of epigenetic mechanisms reveals the importance of DNA remodeling for gene transcription, which is certainly the most fundamental operation of the genome. The transcription of the genome requires dynamic alterations to the chromatin structures within which the DNA operates. Such events involve transient modifications of the histone proteins that determine the accessibility of the DNA. Indeed, cellular signals that increase or decrease gene transcription often function within complexes that include enzymes that directly operate on chromatin. Potentially more stable signals, such as DNA methylation, are also regulated by environmental events and regulate chromatin activity over longer periods. Such epigenetic marks are thus a candidate mechanism for the environmental programming of gene expression. This level of complexity is an essential feature of biology. The ability of an organism to adapt to variations in environmental conditions over the course of its lifespan demands plasticity in genotype–phenotype relations.

The emergence of an integrative developmental perspective has been constrained by historical misunderstandings of the processes by which variations in genomic sequence and nongenomic factors contribute to the development of individual differences in any specific traits. While quantitative behavioral genetics is a valid approach in establishing patterns of familial transmission (i.e., heritability) that *might* imply a causal role for genomic variation, such studies are commonly subject to misinterpretation of genomic influences. The heritability of individual differences could result as a function of nongenomic biological signals such as RNA and protein emanating from the parent as well as from instances where epigenetic modifications enter the germline (Anway, Cupp, Uzumcu, & Skinner, 2005; Jablonka & Lamb, 2005; Vardhman et al., 2003; Whitelaw & Whitelaw, 2006). There are multiple processes by which individual differences in complex traits might be transmitted from parent to offspring. Moreover, estimates of the contribution of *either* genetic or environmental influences at the level of individual variation are complicated by the reality of Gene × Environment interactions (Lewontin, 1974). Most troublesome is the obvious disjunction between the definition of genomic influences that derives from statistical models and the actual biological reality of the genome. It is the operation of the genome that directly influences phenotype. The operation of the genome at any phase of the life cycle is an emergent property of the constant and very physical interaction of the genome with environmentally regulated, intracellular signals that directly alter chromatin structure. Thus, function at any level of biology emerges as a function of the continuous dialogue between the genome and its environment. Attempts to parse the influence of genomic and environmental influences on the expression of complex traits are inconsistent with even the most rudimentary understanding of gene function.

These issues are critical for the study of child development. Research in this field guides both the creation and the evaluation of intervention studies (e.g., Fisher et al., 2000; Olds et al., 1998). The science and technology of the genomic era offer remarkable opportunities to enhance the sophistication of our approach to these challenges. We are now positioned to study directly the origins of individual differences in sensitivity/resistance to treatment within the context of intervention studies (Belsky, 1997; Rutter, 2007). Indeed, the many years of remarkable research in child psychology and psychiatry forms the basis for hypothesis-driven studies of candidate Gene × Environment interactions of responses to treatment within the context of intervention studies. Thus, the response of a child to psychosocial interventions, such as those targeting mother–infant attachment, is influenced by the temperament or reactivity of the child (Belsky, 1997). More reactive children also seem to be more sensitive to the quality of the rearing environment (Boyce & Ellis, 2005). The temperament of the child is influenced by the presence of specific genomic variations in genes that encode for proteins involved in the function of the 5-HT and dopamine systems (Auerbach et al., 2002; Ebstein, 2003; Fox et al., 2005; Lakatos et al., 2003). Could such genomic variations mediate the observed effect of child temperament on the response to specific interventions? What might be a more appropriate intervention for "treatment-resistant" populations? A more integrated Gene × Environment approach offers the opportunity to understand clearly the nature of individual differences in vulnerability or resistance for psychopathology and to more effectively target interventions.

The current study, based on all births in Sweden from 1983 to 1991 ($N = 654{,}707$), explored the processes underlying the association between smoking during pregnancy (SDP) and offspring school grades and mathematic proficiency at age 15. The analyses compared relatives who varied in their exposure to SDP and who varied in their genetic relatedness. Although SDP was statistically associated with academic achievement (AA) when comparing unrelated individuals, the results suggest that SDP does not cause poorer academic performance, as full siblings differentially exposed to SDP did not differ in their academic scores. The pattern of results suggests that genetic factors shared by parents and their offspring help explain why offspring exposed to SDP have lower levels of AA.

Maternal smoking during pregnancy (SDP) has been consistently linked with numerous birth complications and problems in the offspring, including unsuccessful pregnancy outcomes, lower intellectual abilities, lower academic achievement (AA), more inattention and hyperactivity problems, and increased antisocial behavior (reviews in Cnattingius, 2004; Huizink & Mulder, 2006; Wakschlag, Pickett, Cook, Benowitz, & Leventhal, 2002). Many researchers have noted that the current state of research suggests the associations are consistent with a causal connection as the findings are frequently consistent across studies, there is some specificity in the outcomes, the associations follow a dose–dependent relation, and basic research (e.g., animal studies) has identified plausible biological mechanisms through which SDP may interfere with development. The interest in exploring the effects of SDP stems from a growing appreciation of the role of prenatal risk factors for later development (e.g., Coe & Lubach, 2008) and the fact that SDP may be one of the most preventable risk factors for poor pregnancy outcomes (Cnattingius, 2004) and later antisocial behavior (Wakschlag et al., 2002).

It is important to note, however, that SDP is correlated with many risk factors that also predict poor outcomes in children. SDP is correlated with psychosocial risks, such as early age at childbearing; parental history of psychopathology and antisocial behavior, low socioeconomic status (SES), poor parenting, and ongoing exposure to parental substance use (reviews in Huizink & Mulder, 2006; Maughan, Taylor, Caspi, & Moffitt, 2004). These correlated risks could confound the association between SDP and offspring adjustment. A number of researchers have also argued that genetic confounds may explain the associations between SDP and offspring adjustment (D'Onofrio et al., 2003; D'Onofrio et al., 2008; Fergusson, 1999; Knopik et al., 2005; Silberg et al., 2003). Behavior genetic studies have documented that genetic factors influence maternal SDP (Agrawal et al., 2008; D'Onofrio et al., D'Onofrio et al., 2003). Genetic factors that influence SDP, such

---

Funding for the study was provided by grants from the Indiana University Faculty Research Support Program, NARSAD, and the Swedish Research Council. Preliminary analyses were presented at the Behavior Genetics Association Conference (June 2007, Amsterdam).

as risk for substance abuse and dependence (Agrawal et al., 2008), could be passed from parents to their offspring and influence the behavior of their offspring. Thus, SDP may not be causally related to offspring behavior, but rather genetic factors shared by both generations could explain the association.

Approaches to Control for Selection Factors

Most studies of SDP have tried to control for selection factors that could lead to both SDP and offspring adjustment by statistically controlling for characteristics of mothers that covary with SDP (e.g., maternal education, SES, and history of delinquency). To date, reviews suggest that the associations between SDP and birth outcomes (Cnattingius, 2004), and antisocial behavior (Wakschlag et al., 2002) remain largely robust to the inclusion of statistical covariates. With respect to the association between SDP and low AA and intellectual abilities, the literature is less conclusive. Numerous studies have found an independent association between SDP and offspring AA when controlling for various familial characteristics (e.g., Butler & Goldstein, 1973; Cornelius, Ryan, Day, Godschmidt, & Willford, 2001; Fogelman & Manor, 1988; Rantakallio, 1983). In contrast, large national cohort (Fergusson & Lloyd, 1991) and nationally representative studies (Batty, Der, & Deary, 2006) suggest the association between SDP and academic problems is completely confounded by covariates, such as detailed measures of maternal intellectual abilities. Ultimately, the use of measured covariates is limited; finding an independent association while controlling for possible confounds can help support a possible causal inference, but it is impossible to know whether every salient confound was included and measured accurately in each study.

Because SDP co-occurs with numerous psychosocial and genetic risks for offspring the effects of SDP are difficult to isolate using standard family research designs. Quasi-experimental studies, approaches that disentangle co-occurring genetic and environmental risks, are therefore required to elucidate the processes through which SDP is associated with poor adjustment (Moffitt, 2005; Rutter, 2007). Because of the inherent limitations and strengths of each approach, converging evidence from multiple designs is needed to infer a causal association (Rutter, Pickles, Murray, & Eaves, 2001).

Researchers must use numerous approaches, including quasi-experimental designs, to study the putative effects of SDP. Recently, a number of genetically informed approaches have been used as quasi-experimental approaches. Two studies of SDP have utilized a Children of Twins design (D'Onofrio et al., 2003; Heath, Kendler, Eaves, & Markell, 1985; Silberg & Eaves, 2004), an approach that helps control for environmental factors that are not measured by comparing cousins differentially exposed to a putative risk factor. In this design environmental factors that influence all cousins (e.g., SES, religious affiliation) are controlled. The approach also accounts for genetic risk passed down from parents to their offspring because the offspring of an identical twin shares 25% of his or her genetic makeup with the offspring of his or her parent's cotwin (socially they are cousins, but genetically they are half siblings), whereas the offspring of a fraternal twin shares 12.5% of his or her genetic makeup with his or her cousin. D'Onofrio et al. (2003) found that the association between SDP and offspring birth weight (BW) was not due to environmental or genetic confounds. Rather, the association appeared to be mediated via environmental risks specifically associated with SDP, consistent with a causal inference. Knopik et al. (2005), however, found that the association between SDP and offspring attention deficit hyperactivity disorder (ADHD) was largely accounted for by genetic and environmental correlates of SDP, not the teratogenic effects of prenatal nicotine exposure.

A number of studies have recently utilized a sibling comparison approach, a design that compares siblings who are differentially exposed to SDP (the mother varied her smoking among her pregnancies). The comparison of siblings within families rules out all unmeasured environmental risks that affect siblings similarly (Rodgers, Cleveland, van den Oord, & Rowe, 2000). The comparison of siblings also controls for genetic factors transmitted from the mother that influence both SDP and AA in offspring (D'Onofrio et al., 2007; Harden et al., 2007; Lahey, D'Onofrio, & Waldman, 2009). This is because each child receives a random draw of their mother's genes through the process of meiosis, regardless of the mother's SDP during each pregnancy. It is also important to note that child effects, including the possibility of active or evocative gene–environment correlation, cannot confound the findings, as it is unlikely that traits in the offspring influence their mother's decision to smoke while pregnant (Rutter, 2007).

Recent use of the approach suggests that the direct effects of SDP on certain outcomes are minimal. D'Onofrio et al. (2008) found no association between SDP and offspring conduct and behavioral problems when comparing differentially exposed offspring. The association between SDP and attention/impulsivity problems was still statistically significant, but the magnitude of the association was greatly reduced when compared with the association among unrelated individuals. Of particular relevance to the current manuscript, Lambe, Hultman, Torrang, MacCabe, and Cnattingius (2006) found that among mothers who varied in their SDP across pregnancies, the risk for poor AA at age 15 was increased in all offspring regardless of whether they were specifically exposed to SDP. The study was a population-based study in Sweden created by merging national registries. The results suggested that the association between SDP and school performance at age 15 was due to unmeasured familial traits that differ between offspring exposed and unexposed to SDP.

The sibling comparison design is limited, however, in its ability to identify the source of the confounds when the risk factors are not associated with the outcome among siblings (D'Onofrio et al., 2008). Comparing siblings differentially exposed to SDP can disconfirm a causal hypothesis (e.g., Lambe et al., 2006), but the design cannot determine why there is a statistical relation between SDP and AA in the population if differentially exposed siblings do not also differ in AA. Researchers must, therefore, use additional, genetically informed approaches to explore whether factors that confound the association between SDP and offspring AA are genetic or environmental in origin. Numerous genetically informed approaches are available (Rutter et al., 2001).

One approach to disentangling the source of the confounds is to compare the magnitude of the association between SDP and offspring AA in groups of relatives who differ in their exposure to SDP and who differ in their genetic relatedness (D'Onofrio et al., 2008). When multiple types of relatives are included in a study (e.g., cousins, full siblings, and half siblings), researchers can examine whether the degree to which the groups of relatives share genetic risk moderates the association between SDP and AA (i.e., the degree to which relatives share genetic background influences how strongly SDP and AA are associated). If the association between SDP and AA is smaller when comparing groups of relatives who share more genetic background, then genetic factors would be implicated. Stated differently, if the magnitude of the association between SDP and AA is smaller when using comparison groups that better "control" for genetic risk (comparing groups of relatives who share more genetic background), the results would suggest that genetic factors help account for the statistical relation between SDP and AA that is found in the population.

When large family pedigrees are available, researchers can compare two types of cousins who are differentially exposed to SDP. Like children of fraternal twins, cousins whose mothers are full siblings share 12.5% of their genetic makeup (referred to as full cousins), whereas cousins of mothers who are half siblings provide a comparison group that shares only 6.25% of their genes (half cousins). Using full and half cousins, therefore, provides two groups of relatives who differ in the degree to which they share genetic risk; the comparison of full cousins would "control" for (or "account" for) more genetic risk than the comparison of half cousins.

Using different types of siblings can also help to differentiate the possible underlying mechanisms. The comparison of differentially exposed half siblings from the same mother (siblings who share 25% of their genetic makeup) only controls for genetic factors that are passed down from mothers. In contrast, the comparison of full sibling (offspring who share the same mothers and fathers) differentially exposed to SDP rules out genetic factors passed down from both mothers and fathers (Harden et al., 2007; Lahey et al., 2009). If genetic (or environmental) factors from fathers were important in explaining the association between SDP and AA, the association between SDP and AA would be smaller in full siblings than in half siblings (because the comparison of full siblings controls for more genetic risk). A difference in the associations between SDP and AA when comparing full siblings and half siblings would suggest that paternal effects due to assortative mating (the nonrandom mating of individuals based on similar backgrounds) are important in understanding the effects of SDP.

If the magnitude of the SDP and AA association decreases according to increasing genetic similarity in the groups of relatives (unrelated offspring > cousins sharing 6.25% of their genes > cousins sharing 12.5% of their genes > siblings who share 25% of their genes > siblings sharing 50% of their genes), genetic factors would be implicated. The findings would not prove that genetic factors account for the association because the various groups of relatives can also differ on environmental risk associated with SDP (see the Discussion). In contrast, the results would suggest the importance of environmental confounds (factors that influence both SDP and AA) if the association was of the same magnitude in all the relative groups. Environmental confounds would be implicated because the factors accounting for the association between SDP and AA would not depend on genetic risk associated with SDP. In sum, large family studies including relative groups who vary both in their exposure to SDP and in their genetic relatedness can help to differentiate whether genetic and/or environmental factors account for the statistical relation between SDP and AA.

The Current Study

The current study used a number of statistical and quasi-experimental approaches to explore the underlying causal mechanisms responsible for the association between maternal SDP and offspring AA. The current study expands on the study by Lambe et al. (2006), which compared siblings differentially exposed to SDP on school grades using offspring born in Sweden between 1983 and 1987. We use a larger sample to explore the association between SDP and grade average (using data on every individual born in Sweden between 1983 and 1991), include scores from a standardized assessment of mathematic proficiency given to all students in Grade 9 throughout the country, explore the possible confounding role of measured maternal and paternal characteristics, and utilize multiple quasi-experimental designs to help specify the causal mechanisms through which SDP is associated with lower AA.

There were four specific aims of the analyses: (a) identify the magnitude of the associations between SDP and two measures of AA, school grades and mathematics proficiency at age 15; (b) examine whether the relations were robust to the inclusion of statistical covariates for individual, maternal, and paternal characteristics; (c) explore the strength of the associations when comparing cousins and siblings differentially exposed to SDP; and (d) test whether genetic and/or environmental confounds help explain the statistical association between SDP and AA. The last aim was based on our ability to explore whether the strength of the statistical association between SDP and AA was dependent on the degree to which the exposed and unexposed individuals shared genetic risk. The analyses explicitly tested whether the association between SDP and AA was stronger when comparing cousins who share 6.25% of their genes (cousins of mothers who were half siblings) than when comparing cousins who share 12.5% of their genes (cousins of mothers who were full siblings). Likewise, the analyses explored whether SDP was more strongly associated with AA in half siblings (who share 25% of their genes) than in full siblings (who share 50%) who were differentially exposed to SDP.

Method

Sample

The current study was based on merging numerous Swedish population registries. Various governmental agencies and research institutes in Sweden maintain the registries. Each register includes a unique identifier for each individual in the country, which enables Statistics Sweden to link the various data sets. The registries and the agencies that maintain them are described in detail below (see Figure A1 in the Appendix for a diagram of the registries included).

The Medical Birth Register. The Swedish Medical Birth Register (MBR) is administered by the Swedish Centre for Epidemiology at the National Board of Health and Welfare. The MBR includes over 99% of all births in Sweden since 1973 (Swedish Centre for Epidemiology, 2001). Information is gathered throughout the pregnancy and delivery using standardized records. Since 1982, the register has also included information from the first visit to antenatal care. Over 95% of pregnant women in Sweden receive such care by the 15th gestational week (Lindmark & Cnattingius, 1991). The register includes detailed demographic and pregnancy information, including maternal age at birth, maternal living situation, maternal SDP, birth order of the child, infant physical attributes at birth, pregnancy complications, and delivery complications. No offspring who died at childbirth, had serious malformations at birth, and/or were missing the identification number of their mother were included. Because the current study explores prenatal risk factors, all multiple births (e.g., twins and triplets) were entirely excluded from the analyses. Children born in Sweden from 1983 to 1991 were included ($n = 918{,}028$).

The National School Register. The School Register, a collaboration between the Swedish School Authority and Statistics Sweden, includes educational achievement (scores in multiple subjects and summary grades) for all students at the end of Grade 9 (Swedish National Agency for Education, n.d.). The register began in 1983. The analyses in the current manuscript were conducted on information from students in all public and private schools throughout the country between 1998 and 2006. If students repeated the grade, the student's scores for his or her 1st year were used. The total School Register included grades for 972,979 individuals, including some individuals not included in the current analyses (e.g., those from multiple births and children who immigrated to Sweden).

Starting in 2003, all students in Grade 9 throughout Sweden completed a compulsory comprehensive test that provides standardized assessments of students' proficiency in Swedish, English, and mathematics. Thus, the standardized testing permits the comparison of students throughout Sweden on the same test. Scores were available for 456,007 students (from 2003 to 2006).

The National Crime Register. The National Crime Register is maintained by the Swedish National Council for Crime Prevention and includes all registered convictions in the country from 1973 to 2004. The register includes detailed information about the nature of every conviction, number of offenses, time of the criminal activity, and sentence type and length. Merging the data set in the study provided criminal background information from age 15 (age of criminal responsibility) for all of the mothers and fathers of the offspring born in Sweden from 1983 to 1991.

The Education Register. The Education Register is maintained by Statistics Sweden and includes information about the highest obtained level of education for each individual each year since 1990. We used the highest level of education in 2004 for the mothers and fathers of the target children in the study.

The 1990 Census. The Swedish Population and Housing Census were undertaken every 10 years until 1990. Its completion was enforced by law, and it included measures of individuals in each household, such as assessments of employment, occupation, and income. Occupational status information was obtained for individuals from the 1990 Census.

Multi-Generation Register. The Multi-Generation Register, maintained by Statistics Sweden, contains information on the identity of the parents of each child born in Sweden since 1932, or who immigrated and became Swedish citizens before age 18 (Statistics Sweden, 2003). The register is part of the Total Population Register, which collects information from the national registration records maintained by the National Tax Board. For each target individual, the register includes information on the identification number of biological parents and adoptive parents, if appropriate. The information allows researchers to link all children to their parents and identify all types of relationships for each index person (e.g., full siblings, half siblings, grandparents, cousins). Because some of our analyses comprise comparisons among cousins, offspring who had missing information about the identification of their maternal grandmother (e.g., their mother immigrated to Sweden from another country) were not included in the analyses.

Total sample and subsets included in analyses. The total sample used for analyses included 654,707 offspring with information on maternal SDP and at least one of the educational outcomes (either school grades from 1998 to 2006 or standardized testing from 2003 to 2006). The population included 469,182 individual mothers from 397,524 extended families (based on maternal lineage). See Figure A1 in the Appendix for more details.

The first subset of the data included unrelated offspring so that the between families effect of SDP on AA could be estimated. One grandchild from each extended family, indexed by the maternal grandmother, was initially selected. Offspring who shared any first-degree relative (e.g., their father) or second-degree relatives (e.g., their maternal grandfather, paternal grandmother, or grandfather) were excluded from the analyses. The highest genetic relatedness of any two offspring in the sample, therefore, would be minimal (second cousins, $r_g = .5^5 = .03125$). The unrelated subset included 301,823 offspring from the same number of mothers and maternal grandmothers.

The second subset of data was selected to compare cousins, especially cousins differentially exposed to mothers with a history of any SDP. Because the current study explores the putative effects of a maternal behavior, SDP, the identification of cousins was based on offspring of female sisters (i.e., each offspring in an extended family shared the same maternal grandmother). All offspring from extended families with two adult sisters were included in the analyses. Offspring of women with no adult sisters were excluded from the analyses because their offspring had no cousins who were related through maternal aunts. For extended families that contained more than two adult sisters, two adult women and their offspring were selected. If all the women in the extended family had similar histories of SDP (either never smoked during any pregnancy or smoked during every one) then the first two adult sisters and their families were included in the analyses. If there was any variability in SDP histories among the sisters (one woman had a history of ever SDP and one of her adult sisters did not) one adult sister with a history of SDP and one adult sister without and their offspring were included. The subset maximized, where possible, the number of cousins differentially exposed to mothers with histories of SDP. The subset, referred to as the cousin subset, included 181,219 offspring from 126,192 mothers and 63,096 maternal grandmothers.

The third subset of the data sought to compare siblings differentially exposed to SDP. The identification of siblings was based on sharing the same biological mother. All nuclear families that included only one offspring were excluded. All nuclear families with two children were included. If a woman had more than two children, two children were selected for inclusion in the subset. For mothers with no variation in their SDP across their pregnancies, her first two children were selected. For mothers who varied their SDP across their pregnancies, siblings were selected to include one offspring unexposed and one offspring exposed. The subset, referred to as the sibling subset, included 327,346 offspring from 163,673 mothers and 136,358 maternal grandmothers.

Variables

Offspring outcomes. School performance was based on a summary grade point score of 16 different subjects from the National School Register. Students were given separate grades (10 = pass, 15 = pass with distinction, and 20 = pass with honors) for each subject. The summary grade point score summed the subject scores for each student. As was found in previous studies (Lambe et al., 2006), the average grade point score in the population (M = 204.5, SD = 64.3, n = 761,970) was skewed toward higher values. Therefore, the variable was normalized using a Blom transformation, a procedure that has been shown to help when analyzing skewed data using genetically informed designs (van den Oord et al., 2000). The score was then converted to a z score for ease of interpretation.

The compulsory standardized testing of students in Grade 9 provided assessment of student proficiency in mathematics (n = 331,093). Students could receive four possible scores: goals not achieved (10.6%), pass with lowest pass grade (52.1%), pass with distinction or intermediate pass (26.4%), and pass with special distinction or highest pass grade (11.0%). The variable was transformed using a Blom transformation and standardized as a z score.

One birth characteristic, BW as measured in grams, was also included in the current study as a sensitivity analysis because previous findings strongly suggest SDP has a direct effect on offspring BW (e.g., Cnattingius, 2004). Offspring BW, excluding multiple births and children with significant physical malformations, was approximately normally distributed (M = 3,522.5 g, SD = 539.7, n = 759,627). Because BW was measured on an interpretable scale, no transformations were completed.

Risk factors. Maternal SDP was measured on a 3-point scale: nonsmokers, 1–9 cigarettes per day (moderate smokers), and 10+ cigarettes per day (heavy smokers). Given the complexity of the analyses, the analyses treated SDP as dichotomous (no smoking vs. smoking). As has been reported earlier (Cnattingius, 2004), the prevalence of SDP declined during the years of 1983–1992; women reported smoking during 31.3% of pregnancies in 1983 and 24.3% in 1992.

Risk factors specific to each pregnancy were also included. The MBR assessed maternal age at the time of birth, birth order, gestational age (in days), year of birth, and whether the mother was living with a partner at the time of birth, coded as not cohabiting versus cohabiting. Paternal age at the birth of the child was calculated based on his and the child's dates of birth.

Characteristics of the mothers and fathers were also included in the analyses. SES for both parents was measured by a frequently used, standard socioeconomic index variable, based on occupational group (Statistics Sweden, 1982). The groupings include (a) unskilled blue collar worker, (b) skilled blue collar worker, (c) low-level white collar worker, (d) intermediate-level white collar worker, (e) high-level white collar worker, (f) self-employed, (g) employed but uncategorized, and (h) not working/missing. The final category included individuals with no information about occupational status. It includes individuals too young to be assessed (below the age of 15) and individuals that were not working at the time of the census (because they were students or unemployed). Mothers and fathers' SES was based on the occupation of each individual separately. Previous research has shown that the groupings cannot be ordered (Lichtenstein, Pedersen, & McClearn, 1992). Therefore, dummy codes were created to compare each occupational group to the unskilled blue collar worker category.

Maternal and paternal highest level of education in 2004 was based on seven categories: (a) less than 9 years of primary and lower secondary education, (b) 9 years of primary and lower secondary education, (c) 1–2 years of upper secondary education, (d) 3 years of upper secondary education, (e) less than 3 years of postsecondary education, (f) more than 3 years of postsecondary education, and (g) postgraduate education. Because the assessment of educational level was not on an interval scale, dummy codes were used to compare higher levels of education to having completed less than 9 years of primary education. History of criminal behavior for mothers and fathers was based on the presence or absence of a conviction for any criminal offense in the National Crime Register through 2004.

Estimates of genetic relatedness. The biological mother of each offspring was determined by the MBR. The Multi-Generation Register provided information about the biological father of each child. From the information, two offspring from the same mother could be designated as full siblings (sharing the same biological father) or half siblings (having different biological fathers).

The determination of genetic relatedness of cousins was based on information from the Multi-Generation Register. The genetic relatedness of the cousins is based on the genetic correlations of adult sisters within an extended family (the mothers of the offspring in the current study). Genetic relatedness of the adult sisters in the study was determined contingent on their mothers, the maternal grandmothers of the offspring in the current study. Adult sisters who shared the same fathers (the maternal grandfather of the offspring in the study) were determined to be full siblings (sharing 50% of their genetic makeup), whereas adult sisters with different fathers were designated as half siblings (sharing 25% of their genetic makeup). Thus, offspring of full siblings, referred to as full cousins, shared 12.5% of their genes with their cousins, whereas offspring of half siblings, referred to as half cousins, shared 6.25% of their genes with their cousins. The process of determining the relationship of adult sisters contingent on the maternal grandmother does not include aunts who are half siblings because they had the same father but were born to different mothers. We restricted the sample to only include aunts who shared the same mother because the analyses explored the risk of a maternal characteristic (SDP) and we wanted to control for environmental factors that may be shared by women growing up in the same household; most children historically have lived with their mothers after separations or divorces.

Analyses

Association between SDP and risk factors. Linear and logistic regression models estimated the association between SDP and the risk factors at the individual, maternal, and paternal levels. Clustering for extended family members was taken into account using a sandwich estimator and full information maximum likelihood (review in Schafer & Graham, 2002) was utilized to account for missing data using the software program Mplus (Muthén & Muthén, 1998–2007).

Comparison of offspring exposed and unexposed to SDP contingent on biological relatedness. To describe the association between SDP and the AA variables and the underlying processes, the mean AA scores are presented for offspring differentially exposed using the three subsets of the data: unrelated offspring, cousins, and siblings. The difference between the AA means suggest the magnitude of the association between SDP and each academic measure. Formal significance testing of the differences was completed using regression analyses (see the next section). The key to understanding the underlying causal mechanisms associated with SDP stems from the difference in exposure, not the overall mean levels, which are heavily influenced by family type. The means for AA among offspring differentially exposed (e.g., cousins and siblings who varied in their exposure) are tabled.

The first comparison involved unrelated offspring who were exposed and unexposed to SDP. The difference between those exposed and unexposed represents the association between SDP and each AA variable in standard deviation units (the AA variables were converted to z scores). The comparison of cousins differentially exposed to mothers with a history of SDP, regardless of genetic relatedness, was then completed. The comparison controlled for factors influencing all offspring within an extended family. Next, the cousin comparison was estimated separately for full cousins (those sharing 12.5% of their genes) and half cousins (sharing 6.25% of their genes) to examine whether the genetic relatedness of the cousins moderated the association between SDP and AA.

Mean comparisons were then estimated for differentially exposed siblings, regardless of genetic relatedness. Because the identification of siblings was based on sharing the same mother in the current sample, the comparison controls for genetic factors passed from the mother to her offspring, as well as environmental factors shared by siblings. Next, the sibling comparison was calculated separately for full siblings (those who share 50% of their genes) and half siblings (those only sharing 25% of their genetic makeup) to examine the possible influence of paternal factors.

Regression analyses of the relations between SDP and offspring AA. A series of regression analyses were performed to formally test the associations between SDP and AA across the groups of relatives and include the statistical covariates. Five regression models were fit for school grades and math proficiency. Descriptions of the models, including the main parameters of interest, an explanation of the models, and the samples utilized, are found in Table 1. All models accounted for the clustering of the data and used full information maximum likelihood to handle missing values using Mplus (Muthén & Muthén, 1998–2007). Model 1, an epidemiological model, examined the magnitude of the association between SDP and school grades in the entire sample, controlling for offspring sex. Model 2, the standard approach for controlling for selection factors, estimated the association of SDP and grades in the full sample while statistically controlling for the measured covariates.

Model 3 examined the association when comparing cousins and siblings differentially exposed

Table 1
Description of Analytical Models

Description	Parameters of interest	Explanation	Sample used and controls
1. Epidemiological model	SDP parameter	Estimates the difference in AA between unrelated offspring exposed and unexposed to SDP	Includes all offspring in entire data set
2. Association controlling for statistical covariates	Compare magnitude of SDP parameter to Model 1	Estimates the independent association between SDP and AA while statistically controlling for covariates	Includes all offspring in the entire data set
3. Cousin and sibling comparison	SDP: cousin comparison SDP: sibling comparison	Estimates whether offspring whose mother had more SDP across her pregnancies have lower AA than their cousins whose mothers had less SDP on average Estimates whether siblings exposed to SDP had lower AA than their siblings who were not exposed	Includes all offspring in entire data set while controlling offspring birth order
4. Comparison of full and half cousins	SDP: half cousins SDP: half cousin–full cousin	Estimates the association between SDP and AA when comparing half cousins (share 6.25% of genetic makeup) who were differentially exposed Estimates the difference in the cousin SDP–AA association between half and full cousins, which was based on the interaction between the cousin parameter and cousin genetic relatedness, coded 0 = half cousin and 1 = full cousin. To calculate the magnitude of the SDP–AA association in full cousins requires adding the two cousin parameters in the model	Includes all offspring from two mothers per extended family while controlling for the main effects of cousin relatedness and offspring birth order
5. Comparison of full and half siblings	SDP: half siblings SDP: half sibling–full sibling	Estimates the association between SDP and AA when comparing half siblings (share 25% of genetic makeup) who were differentially exposed Estimates the difference in the cousin SDP–AA association between half and full siblings, which was based on the interaction between the sibling parameter and sibling genetic relatedness, coded 0 = half sibling and 1 = full sibling. To calculate the magnitude of the SDP–AA association in full siblings requires adding the two sibling parameters in the model	Includes two offspring from all mothers with two or more offspring while controlling for main effects of sibling relatedness and offspring birth order

Note. All models accounted for the clustering in the data using a sandwich estimator in Mplus. Each model also included the main effect of offspring sex. SDP = smoking during pregnancy; AA = academic achievement.

in the full sample while controlling for birth order effects. The models used a series of contrast codes that have been shown to accurately estimate within and between family effects at multiple levels (Neuhaus & McCulloch, 2006). The statistical approach results in parameters equivalent to that of a fixed effects model (Greene, 2003). For further details concerning the analytical approach, including explanations of the coding, see D'Onofrio et al. (2008) and Harden et al. (2007). Sibling comparisons were based on contrast codes created by subtracting the mother's average SDP across all of her pregnancies from the child's specific exposure. For example, if a mother had two children and only smoked during one pregnancy, the exposed sibling would receive a score equal to .50 and the unexposed sibling would receive a contrast code of −.50. The contrast codes, therefore, compare exposure to SDP relative to their sibling's exposure. A similar approach was used to compare cousins. Contrast codes were calculated by subtracting the average level of SDP across all women in an extended family (the adult sisters) from each mother's average SDP across all of her pregnancies. The contrast codes compared siblings from a nuclear family who were more exposed to SDP on average to their cousins who were less exposed to SDP on average. The mean SDP across all cousins was also included in the model because the parameter associated with the variable provides a comparison of unrelated individuals (i.e., the parameter compares cousins who are all exposed to more SDP on average to unrelated sets of cousins who were exposed to less SDP on average). Model 3, therefore, provides estimates of the association between SDP and AA when comparing unrelated individuals, cousins, and siblings.

The next two models were conducted to further explore the cousin comparisons (Model 4) and the sibling comparisons (Model 5). Model 4 specifically examined whether the magnitude of the cousin comparison depended on whether the cousins were full or half cousins. The model was fit to a subset of the data that only included two adult sisters and their offspring from each extended family so that only one cousin comparison could be made per extended family (a conservative approach to handling extended families with more than two adult sisters). The model utilized the contrast coding scheme for cousin comparisons explained above (recalculated for the subset) and the interaction of the contrast coding with a variable that identified whether the cousins were half (coded = 0) or full cousins (coded = 1). The interaction term, therefore, estimated the difference in the magnitudes of the associations between SDP and school grades in the two types of cousin pairs. The parameter associated with the interaction specifically estimated whether cousin type (full vs. half) moderates the association between SDP and AA, providing a statistical test of whether the SDP–AA association was stronger when comparing half cousins than when comparing full cousins (e.g., D'Onofrio et al., 2005). The model also included the main effect of cousin relatedness.

Model 5 explored whether the strength of the association between SDP and school grades varied among full and half siblings. The model was fit to the subset of data that only included two offspring per nuclear family, which permitted one sibling comparison per mother. The sibling comparison contrast code approach described earlier was used (recalculated on the subset). Plus, the interaction of the contrast code with a variable noting the genetic relatedness of the siblings (0 = half siblings, 1 = full siblings) was included in the model (as well as the main effect of sibling type). The parameter associated with the interaction term assessed whether the SDP–AA association differed between full and half siblings.

Comparison of fathers of half siblings differentially exposed to SDP. Studying nuclear families that include half siblings (the siblings had different fathers) who were differentially exposed to SDP provides a unique opportunity to examine risk factors associated with SDP. By comparing the characteristics of the two fathers and the pregnancies that are associated with the mothers SDP allows us to examine whether any pregnancy-specific or paternal risk factors were specifically associated with the pregnancy during which the mother smoked. Therefore, regression models predicting prenatal smoking exposure were fit to a sample of offspring (n = 2,773) from families that included siblings with different biological fathers and differential exposure to SDP.

Sensitivity analyses. A series of analyses examined the robustness of the findings presented in the manuscript and are briefly summarized in the text (full results available upon request).

Results

Association Between SDP and Risk Factors

Table 2 presents the relation between maternal SDP and each risk factor. The associations indicate

Note. All estimates accounted for clustering using a sandwich estimator and were based on full maximum likelihood approaches to account for missing data. OR = odds ratio.

[a] Estimates for the child-specific risks are based on maternal smoking during each specific pregnancy for all births.

[b] Estimates are unique for each individual mother and are based on maternal history of ever smoking during any pregnancy. The associations with paternal characteristics are based on the father of the first child per mother.

***$p < .001$.

that maternal SDP is associated with the covariates at all levels. When exploring each pregnancy, SDP was associated with earlier age at childbearing for parents, shorter gestational age, and a higher likelihood that the mother was not living with a partner at the time of birth.

The association between SDP and maternal, paternal, and familial risks were based on a woman's history of ever smoking across her pregnancies. SDP was associated with maternal occupational status; compared to women in unskilled blue collar jobs, SDP was associated with lower likelihood of working in white collar jobs. SDP was also associated with greater likelihood of being in jobs that were difficult to categorize or being unemployed. SDP was also associated with maternal highest level of educational achievement; women with a history of SDP were less likely to receive secondary and higher levels of education. Being convicted of a criminal offense was also associated with history of SDP. The same general pattern held for paternal risks. SDP was associated with occupational status, highest educational level achieved, and history of criminal offenses in fathers.

Comparison of Offspring Exposed and Unexposed to SDP Contingent on Biological Relatedness

Table 3 presents the mean comparisons of offspring differentially exposed, based on family type. The mean AA scores for offspring from extended and nuclear families with no variation in SDP are

Note. SDP = smoking during pregnancy.

[a] Based on one grandchild per maternal grandmother. No offspring shared any other first or second degree relatives in the subset.

[b] Based on cousins from two aunts from each extended family.

[c] Based on two siblings for each mother. Significance testing of the differences were conducted using regression analyses controlling for clustering in the data and birth order (see Tables 4 and 5).

presented in Table A1 (in the Appendix). The comparison of unrelated offspring suggests a 0.49 *SD* difference in grades associated with exposure to SDP. The comparison of all cousins differentially exposed to mothers with a history of SDP, regardless of genetic relatedness, suggests the association is attenuated (compared to the study of unrelated individuals), as the difference between the exposed and unexposed was approximately 0.25 *SD*. The comparison of full cousins was comparable (0.24 *SD* difference), but the comparison of half cousins yielded a larger difference (0.32 *SD*), suggesting that the degree of genetic relatedness moderates the association.

The comparison of differentially exposed siblings suggests SDP is not associated with lower grades. When all siblings, regardless of genetic relatedness, are compared there was no difference (exposure is associated with a 0.03 *SD* increase in grades). The comparison of full siblings revealed a similar difference (0.03 *SD* increase). In contrast, the comparison of half siblings (−0.09 *SD*) suggests that SDP is associated with offspring grades when comparing siblings with different fathers.

The same pattern of results was true when comparing the math proficiency scores. The comparison of unrelated individuals revealed a large difference (0.38 *SD*). The comparison of cousins revealed an attenuated difference that was partially dependent on genetic relatedness (a 0.20 difference in full cousins but a 0.27 difference in half cousins). There was no difference in math proficiency when all siblings were compared (0.02 difference). Similarly, no difference emerged when full siblings were compared (0.02 increase), but the exposure to SDP was associated with poorer math proficiency (0.17 *SD* difference) in half siblings.

The mean comparisons suggested two main findings. First, for both school grades and math proficiency, the comparison of full siblings differentially exposed to SDP, a comparison that controls for genetic and environmental confounds shared by siblings, revealed no differences. This finding strongly suggests that SDP does not cause lower AA; rather, differences between families associated with SDP appear to be responsible. Second, the association between SDP and AA appears to covary with degree of genetic relatedness. Table 3 illustrates how the difference between the exposed and unexposed offspring depended on genetic relatedness. For both measures of AA, the magnitude of the association between SDP and AA declined as genetic relatedness increased, suggesting that genetic factors help to explain the statistical relation between SDP and AA.

Regression Analyses of the Relations Between SDP and Offspring AA

School grades. The results of the regression models for school grades are presented in Table 4. Model 1, an epidemiological model, indicated SDP is associated with a 0.50 *SD* decrease in school grades (given the large sample size, significance values will only be noted when they are not $p < .05$). Model 2, which statistically controlled for the covariates, indicated that SDP was associated with a 0.21 *SD* decrease, independent of the effects of the other covariates in the model (Table A2 in the Appendix includes the parameter estimates for all of the covariates). The results from Model 3, a model that compared all cousins and siblings differentially exposed, show that SDP is associated with lower school grades when comparing unrelated offspring ($b = -.58$). The association is attenuated when comparing cousins ($b = -.26$) but is nonexistent when comparing siblings ($b = .00$, $p = .82$).

The results of the Model 4, a model that assessed whether cousin type moderated the association between SDP and AA, suggest that SDP exposure is more strongly associated with school grades when comparing half cousins ($b = -.31$) than when comparing full cousins ($b = -.23 = -.31 + .08$). It is important to note that the difference ($b = .08$) was statistically significant, indicating that cousin type moderates the association between SDP and school grades.

Model 5 examined whether the association between SDP and AA was stronger in half siblings than in full siblings. The model indicated that the half siblings who were differentially exposed to SDP differed in their school grades ($b = -.08$), whereas full siblings differentially exposed did not differ ($b = .00 = -.08 + .08$). The difference was statistically significant.

Figure 1, Panel A presents the estimates of the association between SDP and school grades separately for the different comparison groups (unrelated offspring, half cousins, full cousins, half siblings, and full siblings). The figure illustrates how the association between SDP and school grades is dependent on the genetic relatedness of the relatives used in the comparisons.

Mathematics proficiency. Model 1 indicated that offspring exposed to SDP performed less well on a standardized mathematics test ($b = -.39$ *SD*). The

$^*p > .05$.

results are presented in Table 5. The association ($b = -.15$) was attenuated when statistically controlling for measured risk factors in Model 2 (see Table A3 in the Appendix). Model 3 indicated that the association between SDP and math scores was smaller when comparing cousins ($b = -.20$) than unrelated individuals, and there was no association when siblings were compared ($b = .00$, $p = .94$). Model 4, which explored whether the magnitude of the cousin comparison was dependent on the type of cousins suggested that the association between SDP and mathematics proficiency was stronger when comparing half cousins ($b = -.25$) than full cousins ($b = -.19 = -.25 + .06$), although the difference between the two cousin types could not be estimated precisely ($p = .14$). Model 5, however, indicated that the association between SDP and math scores is stronger (and statistically different) in half siblings ($b = -.15$) than full siblings ($b = .01 = -.15 + .16$). Figure 1, Panel B shows how the association between SDP and math scores varies across the types of relatives.

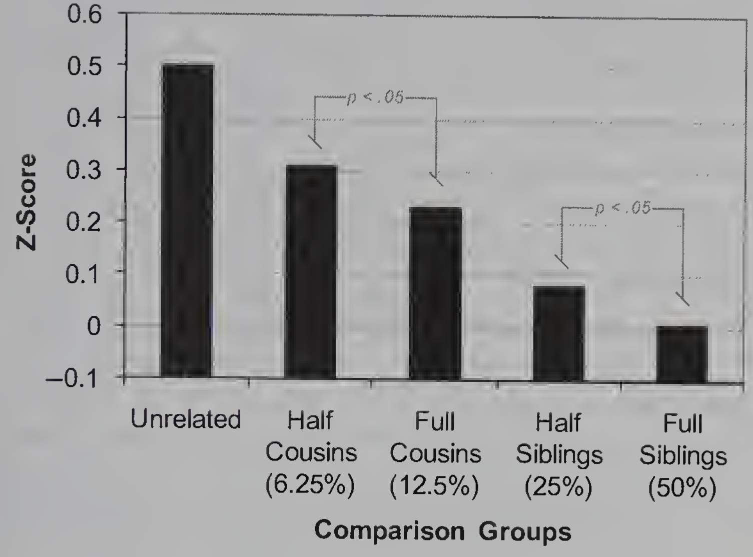
Comparison of Fathers of Half Siblings Differentially Exposed to SDP

The model fitting described earlier suggest that SDP is associated with slightly poorer grades and math scores when comparing siblings who have different fathers. As half and full siblings are equally genetically related to their mothers, the differences in association between SDP and AA for half and full siblings may be due to a genetic correlation between fathers and mothers. A series of regression analyses were conducted to examine which, if any, child-specific and paternal risks factors were associated with the pregnancy during which the mother smoked when the siblings were (a) differentially exposed to SDP and (b) had different fathers ($n = 2{,}773$ births). Birth order, maternal and parental age at childbearing, paternal education, and paternal occupational status were not associated with the pregnancy during which the mother smoked. However, the father of the child who was exposed to SDP was more likely to have a history of criminality (odds ratio [OR] = 1.40, confidence interval [CI] = 1.19–1.62, $p < .05$) and the mother was more likely not to be living with any partner at the time of the birth (OR = 2.05, CI = 1.60–2.63, $p < .05$).

Sensitivity Analyses

A number of additional analyses were performed to test the validity of the findings. Analyses of BW were completed to replicate previous research findings. When comparing unrelated individuals, SDP was associated with a 205-g decrease in BW. The comparison of siblings differentially exposed indicated SDP was associated with a 101-g

A. Grade 9 School Average



B. Grade 9 Mathematics Proficiency

Note. Statistical tests of the differences among the cousin and sibling groups are based on Models 4 and 5, respectively.

decrease. The difference in magnitude of the effect when comparing half and full siblings (20 g) was not statistically significant (p = .32). As no moderation by genetic relatedness was found, the results strongly suggest that SDP has a specific effect on offspring BW.

Results of regression models predicting dichotomous measure AA, a measure of school grades (below passing) using the same cutoff as previous studies (Lambe et al., 2006) and predicting failing mathematics (goals not achieved), were comparable to those reported in the current manuscript (data not shown). Results of analyses using dummy codes to compare moderate smoking and heavy smoking to nonsmokers revealed comparable findings to the results of considering SDP as present versus absent.

Discussion

The current study combined two general quasi-experimental approaches to study the mechanisms through which SDP influences offspring AA. The study relied on the historical decline in SDP, due in part to public health campaigns to deter pregnant women and women of childbearing ages from smoking (Cnattingius, 2004), to explore whether variations in SDP by the same mother were associated with differences in her offspring's AA. The study also utilized a large family study, including a mixture of sibling and cousin types, to compare relatives who differ in their exposure to SDP and who vary in the degree to which they share genetic risk associated with SDP. By combining these two approaches, the current study sought to pull apart the co-occurring genetic and environmental risks associated with SDP.

The results provide support for two main conclusions. First and foremost, the results strongly suggest that SDP does not cause offspring to have lower AA. We compared full siblings who were differentially exposed to SDP, an approach that accounts for the genetic factors and environmental factors that siblings share (Lahey et al., 2009; Rutter, 2007). If SDP causes offspring to have lower AA, perhaps through the neurotoxic effects of exposure to prenatal nicotine, then a child exposed to SDP would be expected to have poorer AA than his or her sibling who was not exposed. For both school grades and mathematics proficiency, however, full siblings differentially exposed to SDP did not differ in their levels of AA. The results strongly suggest that familial risks correlated with SDP, and not the specific effects of SDP, are responsible for the lower AA found in offspring whose mothers smoked during pregnancy. The findings are consistent with previous research on the role of SDP and AA in Sweden (Lambe et al., 2006), as well as a sibling comparison study of conduct problems in the United States (D'Onofrio et al., 2008) and a Children of Twins study of ADHD in Australia (Knopik et al., 2005). The results are also consistent with traditional family studies that used extensive covariates (Batty et al., 2006; Fergusson & Lloyd, 1991). These designs, however, do not explain why SDP is associated with lower levels of AA in the population.

The second conclusion involves the underlying processes by which SDP is associated with AA. The results suggest that genetic factors passed from parents to their offspring (passive gene–environment correlation) account for at least part of the statistical association. Genetic factors are implicated because the degree to which relatives were genetically correlated moderated the association between SDP and AA when comparing types of cousins and types of siblings. Models 4 and 5, in fact, provided statistical tests of these differences. When relatives were more genetically similar (full cousins vs. half cousins and full siblings vs. half siblings), the association between SDP and AA was weaker. Stated differently, when genetic factors were more controlled (by comparing relatives who shared more genetic factors), the association between SDP and AA went down. Figure 1 graphically illustrates this finding. It is important to note that the findings were consistent across levels of analysis (i.e., the comparisons of half vs. full cousins were similar to those comparing full and half siblings) and measures of AA, which provides converging evidence for the confounding role of genetic factors.

We stress that the results do not prove that the underlying causal mechanisms are genetic—the findings only suggest that genetic factors confound the association (i.e., the results are consistent with the role of genetic confounds). Half cousins and full cousins differ in their genetic relatedness, but they also may differ on environmental risks. Full cousins may see each other (and their aunts) more often than half cousins, which could make full cousins more similar if the level of contact influenced AA—the equal environments assumption one generation removed (D'Onofrio et al., 2003). Offspring of half siblings may also be exposed to more environmental risk than offspring of full siblings, which could influence the variability in AA. Similarly, there may be differences in the variability of AA between half and full siblings. These limitations, which apply to all step-family behavioral genetic designs (e.g., Reiss, Neiderhiser, Hetherington, & Plomin, 2000) need to be tested in future studies. Using the Children of Twins design would help test these assumptions. Studies of adult twins frequently include measures of contact between the twins (and their families), which could help account for differences in levels of family contact. Differences in genetic risk among cousins also would not be based on comparing offspring from intact families to those from divorced or separated parents; rather, differences in genetic relatedness among cousins in the Children of Twins design are due to the zygosity type of the adult twins.

The comparison of fathers of half siblings discordant for exposure to prenatal smoking indicated that the father of the child exposed to SDP more often had a history of criminal convictions. Exposure to prenatal smoking, thus, covaries with paternal risk of criminality, even within families. For the paternal phenotype to influence a genetic association between mother and offspring, the paternal phenotype has to be genetically correlated with the maternal phenotype. It is well known that there is substantial assortative mating for antisocial behavior (e.g., Krueger, Moffitt, Caspi, Bleske, & Silva, 1998), and in the current sample women with a history of a criminal conviction were much more likely to have children with men with convictions (OR = 3.38, CI = 3.32–3.46). Thus, the pattern of associations between SDP and AA for half and full siblings is congruent with genetic confounding, even though environmental explanations cannot be excluded. Additional research is required to further delineate the underlying causal mechanisms.

The fact that SDP is associated with lower AA in half siblings provides compelling evidence that researchers must explore the role of fathers when studying the putative effects of SDP. Although most research on SDP has not included measured characteristics of the fathers (review in Maughan et al., 2004), the current results indicate that characteristics of fathers, whether due to genetic risk passed down to the children or psychosocial risk factors, help explain some of the association between SDP and offspring AA.

In addition to the ability to use quasi-experimental approaches to study the risks associated with SDP, the current study also benefits from a number of key strengths. The study was conducted on a large, national sample of offspring. The analyses also included two measures of AA, school grades and mathematics proficiency. The inclusion of the mathematics scores greatly helps the interpretation of the data because the assessment was standardized across the entire study. School grades could vary substantially by schools or communities. The fact that both measures of AA provide similar results provides converging evidence for the conclusions drawn. The large sample size also permits the comparison of unique types of relatives (e.g., half siblings differentially exposed to SDP) that would be hard to find using traditional samples. SDP was also assessed during pregnancy rather than relying on maternal retrospective reports, a key limitation of some of the previous sibling comparison tests of SDP (Rutter, 2007). The analyses were also able to include measured covariates of both mothers and fathers. The exclusion of paternal information is a key limitation of previous research on SDP (Maughan et al., 2004).

There are also a number of limitations of the current study. The measure of SDP was based on maternal report, usually during the beginning of her pregnancy. Exposure to smoking later in life was also not available. Therefore, the study cannot explore whether the timing of the exposure was critical for later AA. The study could also not explore the importance of paternal SDP. The analyses also did not study whether individual or familial factors moderate the association between SDP and offspring AA. Research has suggested that factors, such as offspring sex and birth complications (Brennan, Grekin, & Mednick, 1999), interact with SDP to substantially increase risk for poor offspring adjustment. The comparison of siblings differentially exposed relies on assumptions that mothers who vary their smoking across pregnancies are comparable to those who smoked during every pregnancy (D'Onofrio et al., 2008). Furthermore, the analyses did not estimate the degree to which environmental and genetic confounds explain the association between SDP and AA. The results imply that genetic factors (and environmental confounds) are important. We are currently working on the analytical models required to specifically quantify the role of genetic and environmental factors when studying exposure to SDP with the various types of relative pairs available. More research, therefore, is needed to understand the causal process responsible for the association between SDP and poor offspring AA.

Overall, the study illustrates the importance of quasi-experimental approaches to studying putative environmental risk factors (Moffitt, 2005; Rutter, 2007). Similar to the two previous sibling comparison studies of SDP (D'Onofrio et al., 2008; Lambe et al., 2006), we would have drawn the wrong conclusion about the role of SDP if we only relied on the statistical covariates to account for confounds. Even though the regression analyses on the epidemiological sample controlled for measures of maternal and paternal traits, we would have wrongly concluded that SDP had an independent association with AA after controlling for maternal and paternal characteristics, consistent with a causal inference.

Finally, it is important to emphasize that the current results do not suggest that SDP has no impact on offspring adjustment. The results are limited to measures of AA at age 15 only. The findings for BW suggest, as have previous genetically informed (D'Onofrio et al., 2003) and other quasi-experimental studies (Cnattingius, 2004), that SDP has a specific effect on offspring BW that is environmentally mediated. SDP appears to impact particular outcomes more strongly than others, particularly poor pregnancy outcomes (Cnattingius, 2004). Reducing SDP, therefore, remains a major public health issue.

Fetal Genotype for the Xenobiotic Metabolizing Enzyme *NQO1* Influences Intrauterine Growth Among Infants Whose Mothers Smoked During Pregnancy

Thomas S. Price

Maternal smoking during pregnancy retards fetal growth and depresses infant birth weight. The magnitude of these effects may be moderated by fetal genotype. The current study investigated maternal smoking, fetal genotype, and fetal growth in a large population sample of dizygotic twins. Maternal smoking retarded fetal growth in a dose-dependent fashion. In a subsample of 497 twin pairs whose mothers smoked during pregnancy, a functional polymorphism in the NAD(P)H:quinone oxidoreductase gene (*NQO1* Pro187Ser; rs1800566) was significantly associated with fetal growth within families. The effect was strongest among moderate smokers. This is the first demonstration that fetal genotype for an enzyme involved in tobacco smoke metabolism influences intrauterine growth independent of maternal genotype. Future studies should conduct formal tests of Fetal Genotype × Maternal Smoking interactions.

Maternal smoking during pregnancy is a well-established and preventable risk factor for low birth weight (< 2,500 g) and its sequelae of poor physical, cognitive and behavioral development, excess morbidity, and increased rates of both perinatal and adult mortality (Kramer, 2003). The primary causes of low birth weight are preterm birth and intrauterine growth restriction (IUGR). The consequences of IUGR include both short-term and long-term morbidity and permanent deficits in growth and neurocognitive development (Kramer, 2003). Epidemiological studies have shown that maternal smoking is associated with both short gestation and IUGR (Kramer, 2003). Mothers who quit smoking while pregnant have longer gestations and heavier newborns than those who continue to smoke (Lumley, Oliver, Chamberlain, & Oakley, 1998). This fact is recognized in public policy: In the United Kingdom, formal smoking cessation programs are recommended as part of antenatal care to prevent low birth weight (Health Development Agency, 2004). This study investigated the effects of fetal genotype on intrauterine growth (IUG) for infants whose mother smoked during pregnancy. The goal was to prioritize candidates for future epidemiological and functional investigation of fetal genotypes that modify the effects of tobacco smoke exposure on fetal growth.

The Role of Xenobiotic Metabolizing Enzymes in Prenatal Smoke Exposure

The placenta provides nutrients to the fetus and acts as a barrier to protect the fetus from foreign substances (known as xenobiotics) in the maternal blood. Direct toxicity in developing fetal cells and the depression of placental function by smoke components are critical factors in the retardation of fetal growth. Mechanistically, smoke components can cause oxidative chemical stress in placental and fetal cells, reduce the placental transport of blood

or nutrients, perturb endocrine placental functions, and induce fetal hypoxemia (blood oxygen deficiency). The authors hypothesize that chemical stress on fetal cells may provide a tractable target in terms of identifying fetal genetic modifiers of tobacco smoke exposure.

Tobacco smoke is a complex mixture of compounds including three important classes of procarcinogens: polycyclic aromatic hydrocarbons, arylamines, and *N*-nitrosamines (Bartsch et al., 2000). Both maternal and fetal cells, in the placenta and other tissues, defend against these harmful substances with a biochemical one-two punch: enzyme-catalyzed Phase I (activation) and Phase II (detoxification) reactions. Phase I enzymes typically introduce a reactive group into the molecule that enables its conjugation in a Phase II reaction. The Phase I intermediate is often more harmful than its precursor and may promote oxidant stress or damage DNA molecules, processes that may mediate the effects of tobacco smoke on fetal growth (Kim et al., 2005; Li & Wang, 2004; Myatt & Cui, 2004). Thus, it is likely that IUG under conditions of smoke exposure is critically dependent on the efficacy with which maternal, fetal, and placental cells can metabolize and eliminate exposure toxins. Indeed, polymorphisms in the xenobiotic metabolizing enzymes that activate and detoxify the components of tobacco smoke have been shown to influence its effects on fetal development. Associations have been reported between fetal growth and maternal variants in genes including *CYP1A1* (Chen et al., 2005; Infante-Rivard, Weinberg, & Guiguet, 2006; Sasaki et al., 2006; Sram et al., 2006; Wang et al., 2002; Wu et al., 2007), *GSTT1* (Infante-Rivard et al., 2006; Wang et al., 2002), *GSTM1* (Sasaki et al., 2006), *AhR* (Sasaki et al., 2006), *CYP2E1* (Sasaki et al., 2008), and *NQO1* (Sasaki et al., 2008). While one would expect that fetal genotype would also modify the effects of maternal smoking, this has only begun to be investigated. Thus, a recent study that assessed the interaction between maternal smoking and fetal genotype reported that newborns carrying one or two deletions of *GSTT1* were at increased risk of being small for gestational age (SGA) if their mothers smoked during pregnancy (Infante-Rivard et al., 2006). These results, however, were not adjusted for the correlated effects of maternal genotype, so it remains unknown whether fetal genotype for xenobiotic metabolizing enzyme genes makes an independent contribution to the susceptibility to smoking-related growth retardation.

The Role of Folate in Prenatal Smoke Exposure

Availability of folate to the fetus in early gestation may also be a significant determinant of infant birth weight and is influenced by both genetic factors and environmental conditions, including smoking. Folate is a micronutrient with critical importance for fetal development. Reduced maternal folate status during pregnancy strongly increases the risk of neural tube defects (Lumley, Watson, Watson, & Bower, 1998). Observational studies (Mitchell et al., 2004; Neggers, Goldenberg, Tamura, Cliver, & Hoffman, 1997; Rao et al., 2001) suggest that folate supplementation may reduce the risk of IUGR and low infant birth weight. Data from controlled trials suggest that folic acid at high doses reduces the risk of low birth weight (pooled relative risk at 0.73; 95% confidence interval [CI] 0.53, 0.99), suggesting that the association is causal (Charles et al., 2005). Studies that have measured maternal folate status directly have also found associations with IUGR (Goldenberg et al., 1992; Steegers-Theunissen, Van Iersel, Peer, Nelen, & Steegers, 2004) and infant birth weight (Relton, Pearce, & Parker, 2005). Moreover, cigarette smokers have lower levels of folate in whole blood, red blood cells, plasma, and serum (Kato et al., 1999; Refsum et al., 2006; Walmsley, Bates, Prentice, & Cole, 1999). Maternal smoking also depletes infant folate (Stark, Pawlosky, Sokol, Hannigan, & Salem, 2007). It is likely that smoking aggravates the effects of poor folate status on fetal growth: There is evidence that the relation between plasma folate levels and IUGR may be stronger in mothers who smoke (Sram, Binkova, Lnenickova, Solansky, & Dejmek, 2005).

The metabolism of folate in vivo is known to be influenced by genetic variation (Fredriksen et al., 2007). The link between folate-related genetic variation and fetal growth, however, is far from clear (Engel, Olshan, Siega-Riz, Savitz, & Chanock, 2006; Franchi et al., 2004; Gebhardt, Scholtz, Hillermann, & Odendaal, 2001; Glanville et al., 2003; Glanville et al., 2006; Infante-Rivard et al., 2002; Kupferminc et al., 1999; Martinelli et al., 2001; McCowan et al., 2003; Murphy et al., 2000; Nurk, Tell, Refsum, Ueland, & Vollset, 2004; Park et al., 2005; Relton, Pearce, Burn, & Parker, 2005; Salomon et al., 2004; Verspyck et al., 2002). The general lack of significant main effects of folate pathway genes on IUGR, however, does not rule out the possibility that folate-related polymorphic variation influences fetal growth by moderating the effects of environmental risk factors such as low folate intake. Several studies have reported associations between folate pathway genotype and fetal growth only among mothers with depleted folate status (Engel et al., 2006; Infante-Rivard et al., 2002; Relton, Pearce, Burn, et al., 2005; one study has reported a significant genotype–environment interaction with maternal folate status, Park et al., 2005). In addition, a fetal polymorphism in a folate pathway gene has been shown to moderate the effects of maternal smoking on risk for neural tube defects (Jensen, Hoess, Whitehead, & Mitchell, 2005). Although the causal mechanisms remain unknown, it is plausible that poor neurodevelopmental outcomes arise because folate genotype and maternal smoking interact mechanistically to reduce levels of circulating folate. Indeed, it has been reported that *MTHFR* C677T, a functional polymorphism in the folate pathway gene methylenetetrahydrofolate reductase, moderates the effect of tobacco exposure on serum folate levels (McDonald, Perkins, Jodouin, & Walker, 2002).

A powerful method of prioritizing genetic candidates when a Gene × Environment interaction (G × E) is suspected is to search for genetic association in a sample of subjects who have been exposed to the relevant environmental risk (Moffitt, Caspi, & Rutter, 2005). The current study tested fetal genetic variants in xenobiotic metabolizing enzymes and folate pathway genes for association with fetal growth in a population sample of dizygotic (DZ) twins born to mothers who smoked during their pregnancy. The focus was on common polymorphisms with known or suspected functional activity in genes responsible for metabolizing components of tobacco smoke (see Table 1). These included the Phase I enzymes epoxide hydrolase (*EPHX1*), cytochrome P450 isoforms *CYP1A2* and *CYP1B1*, the Phase II enzyme glutathione *S*-transferase P (*GSTP1*), and NAD(P)H quinone oxidoreductase (*NQO1*), an enzyme with both Phase I and Phase II activity. It was also hypothesized that the effect of maternal smoking to depress birth weight was moderated by polymorphisms in genes involved in the metabolism of folate, including *MTHFR*, methionine synthase (*MTR*), methionine synthase reductase (*MTRR*), methylenetetrahydrofolate dehydrogenase (*MTHFD1*), cystathione β-synthase (*CBS*), and cytosolic serine hydroxymethyltransferase (*SHMT1*; see Table 1). In addition, it was anticipated that the strength of any genetic association might vary with the dose of tobacco exposure.

Comparing outcomes within families ensured matching within twin pairs for their exposure to tobacco smoke and other risk factors that might account for the association between smoking during pregnancy and IUG. Consequently, this research design eliminated many of the potential confounds present in previous studies. Although

twins tend to have lower birth weights and shorter gestations than singletons due to crowding in the uterus, prenatal exposure to tobacco is reliably associated with lower birth weight (Pollack, Lantz, & Frohna, 2000; Salihu, Aliyu, & Kirby, 2005), and low birth weight is associated with elevated risk of poor developmental outcomes (Aylward, 2005; Rooney, Hay, & Levy, 2003) in both twins and singletons. Because the current study defined IUG as birth weight adjusted for gestational age, the findings may be more likely to generalize to singletons (Morley, 2005).

Method

Sample

The sample is a subset of the Twins Early Development Study (TEDS), a study of all twins born in England and Wales in 1994, 1995, and 1996 (Trouton, Spinath, & Plomin, 2002). From 25,815 live twin births identified by the government organization responsible for birth records, 65.5% of families were contacted, and of these, 81% agreed to participate. Each family received a questionnaire booklet around 18 months after the birth of the twins asking for details about the pregnancy and birth, the health of family members, structure of the family, and other demographic variables. In total, 13,429 families returned the booklet. The families who responded were reasonably representative of parents with young children in the UK population in terms of ethnicity, education, and employment status (Price, 2003). Of these, 6,942 families provided DNA samples for the twins, collected from buccal swabs (Freeman et al., 1997). Zygosity was determined by examining the identity of polymorphic DNA markers. Where DNA was unavailable, zygosity was determined using a standard parental report questionnaire asking about the physical similarity of the twins that has been shown to have 95% accuracy (Price et al., 2000). The full sample ($n = 8{,}918$ pairs) included in these analyses was restricted to DZ pairs and contained 2,233 male–male DZ pairs, 2,123 female–female DZ pairs, and 4,562 male–female pairs.

A subsample of twins whose mothers smoked during pregnancy was selected for genotyping. DNA was available from a total of 145 DZ male–male pairs, 153 DZ female–female pairs, and 246 male–female pairs whose mothers reported smoking during pregnancy in the booklet and who provided DNA samples. One twin pair was excluded from the analysis due to invalid birth weight data. A further 6 pairs were excluded whose gestational age was unknown, and 10 pairs were excluded because maternal alcohol consumption was not reported. A further 30 pairs were excluded because a majority of the genotyping assays failed in the first pass of genotyping for one or other twin, leaving a final sample of 497 twin pairs.

Measures

Birth weight and IUG. Birth weight was reported by parents in the booklet and recorded in either pounds and ounces or in kilograms. These reports were converted to grams ($M = 2{,}516$ g, $SD = 549$ g). Reported birth weights of less than 500 g ($n = 11$) were excluded from the data: The World Health Organization recommends excluding children below this threshold from statistics for live births due to near 100% mortality (Cartlidge & Stewart, 1995). Reported birth weights in excess of 5,000 g ($n = 6$) were treated as extreme outliers and excluded from the data set. Male twins tended to be about 100 g heavier than female twins (DZ male–male pairs: $M = 2{,}549$ g, $SD = 551$ g; DZ female–female pairs: $M = 2{,}456$ g, $SD = 542$ g; males in opposite-sex pairs: $M = 2{,}581$ g, $SD = 562$ g; females in opposite-sex pairs: $M = 2{,}457$ g, $SD = 546$ g). IUG was defined as birth weight corrected for gestational age. The expected birth weight given gestational age was calculated using a nonparametric smoothing method (local quadratic regression with a smoothing span of 0.75). IUG ranged from −2,227 to 2,088 g ($M = -11$ g, $SD = 391$ g) and was approximately normally distributed after correcting for the effects of twin sex and birth order (skewness = 0.08, kurtosis = 1.03). Importantly, intrapair differences in IUG were also approximately normally distributed after correcting for sex and birth order (skewness = −0.01, kurtosis = 0.58).

Smoking during pregnancy. A section of the booklet sent to parents approximately 18 months after the twins were born was devoted to features of the mother's pregnancy with the twins and the twins' early life. One question asked the mother to report whether she smoked during the pregnancy; 19.1% of mothers responded that they did. If the mother endorsed this item, she was asked to report the trimester or trimesters in which she smoked and how many cigarettes per day she smoked on average. The number of cigarettes mothers reported smoking ranged from 1 to 40 ($M = 10.5$, $SD = 6.1$). For the purposes of these analyses, the quantity of tobacco was recoded into an ordinal variable with the following categories: smoked less than 10 cigarettes per day ("moderate smokers"; 36.9%), smoked 10 or more cigarettes per day ("heavy smokers"; 63.1%).

Demographic and maternal covariates. Several covariates were investigated as possible confounders of the relation between smoking and IUG. The covariates were dichotomous and measured at the family level. Frequencies of the covariates were: alcohol consumption (mother reported drinking 1 or more units of alcohol per week): 27.0%; ethnicity reported as other than "White": 7.1%; mother reported education to "A" level standard (a qualification equivalent to a high school diploma): 33.0%; twins were the oldest children in the family home (a proxy for primiparity): 47.7%; twins were delivered by Caesarian section: 46.2%; mother reported suffering from high blood pressure during the pregnancy: 24.4%; mother reported suffering from diabetes during the pregnancy: 2.6%; mother reported suffering from pre-eclampsia during the pregnancy (a condition that can be dangerous to both mother and baby, characterized by high blood pressure and the presence of protein in the urine): 9.5%.

Genotyping was performed on a subsample of the DZ offspring of mothers who smoked during pregnancy and for whom DNA samples were available, as described previously. Only common single nucleotide polymorphisms (SNPs) with proven or suspected functional activity in xenobiotic metabolizing enzymes and folate pathway genes were selected for genotyping. With one exception (rs234706) these were nonsynonymous variants causing an alteration in the amino acid sequence of the encoded protein. Non-SNP variants, such as insertions, deletions, and variable number repeat polymorphisms, could not be genotyped using the technology that was employed. SNPs with an estimated minor allele frequency in European populations of less than .1 were not genotyped because of low statistical power to test hypotheses relating to rare variants.

Genotyping was performed at the University of Pennsylvania School of Medicine Molecular Genotyping and Diagnosis Core Facility using a standard protocol (Rennert et al., 2005). TaqMan 5′ nuclease PCR primers and probes for alleles of the variant of interest were obtained from Applied Biosystems (ABI, Foster City, CA). Each probe consisted of an oligonucleotide with a fluorescent reporter dye, a nonfluorescent quencher, and minor groove binder (MGB). Allele-specific cleavage of probes was detected using different reporter dyes for each probe (6FAM and VIC fluorophores for each allele) with separate wavelength maxima. PCR amplifications were set up in a 384-well plate format in total volume of 5 μl, containing 50–900 nM of each primer, 50–250 nM of each probe, TaqMan Universal Master Mix (ABI) and constant dilutions of 5 ng of DNA sample for assays by design. PCR amplifications were set up in a 384-well plate format in total volume of 5 μl, containing 2.5 μl 2× universal master mix, 0.25 μl 1× primer and probe from ABI and 2.25 μl of DNA at a concentration of 5 ng/μl. Controls representing each genotype for each variant and a no template (water) control were included in each 384-well plate. PCR was performed in ABI 7900 HT Sequence Detection System (ABI). After an enzyme activation step for 10 min at 95°C, 60 two-step cycles were performed; 15 s denaturation at 95°C followed by 1 min annealing/extension at 60°C for all variants. After PCR endpoint, fluorescence levels of 6FAM and VIC were measured automatically in each well using the SDS 2.1 manufacturer's custom software (ABI). Allelic discrimination results were then graphed on a scatter plot contrasting reporter dye florescence for one allele against the other.

In 30 of the genotyped individuals (all in different families) a majority of the genotyping assays failed in the first pass of genotyping, probably because the DNA sample was low in volume or of poor quality. After excluding these families, no individual in the final sample had more than three genotyping failures. All of these failed assays were repeated twice. After repeating the failed genotyping assays, there were only three missing genotypes in the data set.

Statistical analysis proceeded in two parts. In the first part, the association between smoking during pregnancy and offspring IUG was tested in the overall sample. In the second part, tests of association between fetal genotype and IUG were conducted in the genotyped subsample using an adaptation of the statistical model implemented in the program QTDT (Abecasis, Cardon, & Cookson, 2000; Fulker, Cherny, Sham, & Hewitt, 1999). The QTDT model tests the association between IUG and genotype both within and between families assuming that IUG in twin pairs follows a bivariate normal distribution. The test of association between families is equivalent to calculating the average IUG values for each twin pair in the sample and regressing this on the average genotype values. The test of association within families is equivalent to regressing the within-pair differences in IUG on the within-pair differences in genotype. In this model, the genetic association between families is biased in the presence of stratification (confounding due to admixture between ethnic populations with differing allele frequencies and mean IUG), but the association within families is not. Furthermore, the mean sibling genotype, as estimated in tests of the between-families effect, is confounded with maternal genotype. As a result, the estimate of the genetic association with IUG between families may include effects of maternal genotype as well as fetal genotype. The QTDT model allows a test of the heterogeneity of between- and within-family effects (Abecasis et al., 2000; Fulker et al., 1999; implemented as the "stratification" association model in the original software, http://www.sph.umich.edu/csg/abecasis/QTDT): The null hypothesis, in this instance, is that the effects of stratification and maternal genotype are absent or cancel each other out. Under the null hypothesis, the effects of fetal genotype can be estimated both between and within families. Otherwise, only the within-family test is appropriate.

Birth weight was adjusted for gestational age, twin sex, and for a set of familial and gestational covariates measuring maternal alcohol consumption, ethnicity, maternal education, primiparity, birth by Caesarian section, maternal high blood pressure, diabetes, and toxemia/pre-eclampsia. Two coefficients were estimated for each of these covariates: one coefficient for its shared environmental effect and another coefficient for its effect on the birth order difference in birth weight. Similar coefficients were also estimated for the effects of smoking dose, considered as a binary variable (mother smoked 10 or more cigarettes per day). Likelihood ratio tests comparing nested models were performed to test the principal hypothesis of an additive main effect of genotype on IUG and an interactive effect of genotype with smoking dose (2 *df* tests). The 2 *df* test has been recommended as the most powerful method to screen for genetic associations when G × E is likely, but the true G × E model is not known (Kraft, Yen, Stram, Morrison, & Gauderman, 2007).

For each SNP, an initial test of the heterogeneity of between- and within-family effects was performed. If this test was nonsignificant using $\alpha = .05$, the effects of fetal genotype both within and between families were estimated according to the "total" model. If the test of heterogeneity was significant, the effects of fetal genotype were estimated within families only (the "within-families" model, equivalent to the "orthogonal" model in the original QTDT). Post hoc analyses tested the following hypotheses: (a) additive main effect of genotype (1 *df* test); (b) additive G × E in the presence of an additive main effect (1 *df* test); and (c) effects of genetic nonadditivity, following Posthuma, de Geus, Boomsma, and Neale (2004) (4 *df* test). All tests were conducted under the assumption of no linkage because there was insufficient information from the small number of SNPs tested to estimate the numbers of alleles identical by descent with accuracy.

Statistical analyses were conducted using the freely distributed software packages *R* for Windows version 2.6.1 (R Development Core Team, 2007) and *Mx* for Windows (*MxGUI* version 1.7.03; Neale, Boker, Xie, & Maes, 2003).

Results

Is Smoking During Pregnancy Associated With IUG in the TEDS Sample Overall?

In the sample overall, children whose mothers smoked weighed 152 g less at birth than children whose mothers did not smoke, $t(8{,}197\ df) = -16.7$, $p < .0001$, after controlling for gestational age and twin sex. The offspring of heavy smokers (10 or more cigarettes per day) weighed 167 g less than offspring of nonsmokers, whereas the offspring of moderate smokers weighed 126 g less than offspring of nonsmokers, after controlling for gestational age and twin sex, indicating a significant effect of tobacco dose on IUG, $t(8{,}196\ df) = -2.4$, $p = .01$.

Is the Relation Between Smoking During Pregnancy and IUG Confounded by Family or Maternal Characteristics in the TEDS Sample Overall?

After adjusting for the effects of twin sex, higher IUG was associated with white ethnicity, more educated mothers, primiparity, maternal diabetes, and the absence of toxemia and pre-eclampsia during the pregnancy (all $ps < .05$). Firstborn twins were, on average, 22 g heavier than their younger cotwin. The birth-order effect was greater for mothers who were not nulliparous (i.e., in families with older children), in mothers reporting high blood pressure and toxemia/pre-eclampsia, and in children born by Caesarian section, after adjusting for twin sex (all $p < .05$).

After controlling for the effects of twin sex and the entire set of covariates, the effect of maternal smoking on IUG remained statistically significant, reducing IUG by 159 g compared to the offspring of nonsmokers, $t(8{,}005\ df) = -17.3$, $p < .0001$. The additional impact of heavy smoking (a reduction of 185 g compared to nonsmokers) over moderate smoking (a reduction of 118 g compared to nonsmokers) also remained significant, $t(8{,}004\ df) = -3.9$, $p < .0001$.

Is Fetal Genotype Associated With IUG Among Twins Whose Mothers Smoked During Pregnancy?

Among mothers in the genotyped sample, 192 mothers (38.6%) reported smoking fewer than 10 cigarettes per day; 305 mothers (61.4%) reported smoking 10 cigarettes or more per day. These proportions were very similar to those for mothers in the entire sampling frame who reported smoking during the pregnancy. The dose effect of smoking was comparable to that in the sample overall. Heavy smoking was associated with a reduction in IUG of 62 g relative to moderate smoking, after controlling for gestational age, twin sex, and maternal and familial characteristics, $t(486\ df) = -1.9$, $p = .05$.

The genotype frequencies and test of Hardy–Weinberg Equilibrium (HWE) are shown in Table 1. Minor allele frequencies (MAF) ranged from .09 to .48. None of the SNPs deviated from HWE at $\alpha = .05$ according to the QLHW test that is valid in samples of related individuals (Bourgain, Abney, Schneider, Ober, & McPeek, 2004). The two markers in *MTHFR* were in linkage disequilibrium although they were not highly correlated ($D' = 1.00$, $r^2 = .22$); the same was true for the two SNPs in *CYP1B1* ($D' = .99$, $r^2 = .18$). In contrast, there was evidence of substantial recombination between the two polymorphisms in the *EPHX1* gene ($D' = 0.03$, $r^2 = .00$).

Tests of genetic association with IUG were conducted using a modification of the QTDT regression model (Posthuma et al., 2004) that allows for moderation of the genetic effect by smoking dose (see Table 1). There was evidence for a significant association between *NQO1* Pro187Ser (rs1800566) and IUG within families, $-2LL\ (2\ df) = 11.76$, $p = .0028$. This result remained statistically significant ($p = .042$) after Bonferroni correction for multiple testing (15 tests). The association between the variant *NQO1* allele and IUG within families reached nominal levels of statistical significance when the data were reanalyzed using reported tobacco intake as a quantitative variable, $-2LL\ (2\ df) = 8.92$, $p = .012$. Post hoc testing revealed that the main, $-2LL\ (1\ df) = 7.79$, $p = .0052$, and interactive effects, $-2LL\ (1\ df) = 3.96$, $p = .047$, of the rs1800566 SNP were both statistically significant. In twins whose mothers were moderate smokers during pregnancy (less than 10 cigarettes per day), possession of one more Ser allele than one's cotwin was associated with a 178 g elevation in birth weight relative to the cotwin, after correcting for twin sex, maternal and familial characteristics, and birth-order effects (see Figure 1). The association was absent in the offspring of heavy smokers. There was no evidence of genetic nonadditivity. Both the main effect and the interaction remained significant when the set of familial covariates was removed from the model. No other SNPs achieved even nominal levels of significance.

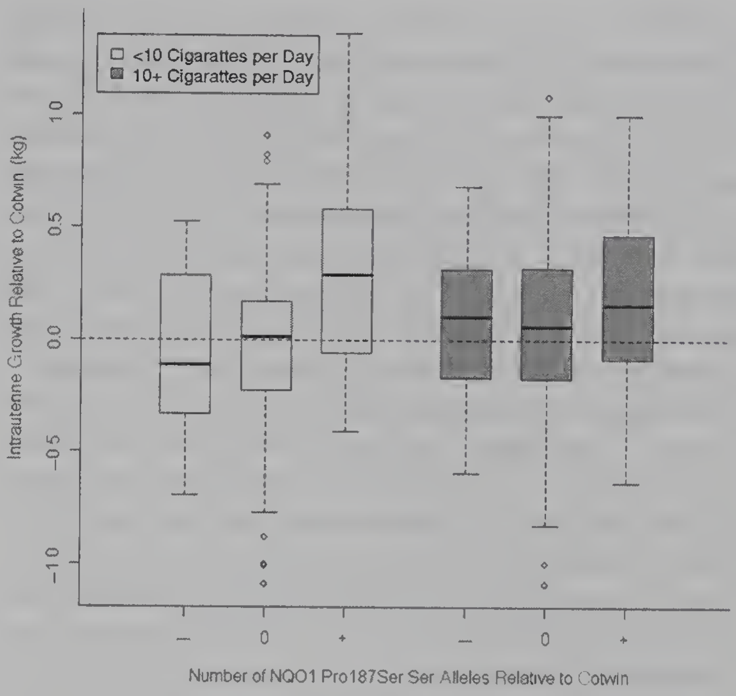

Figure 1. Effect of *NQO1* Pro187Ser (rs1800566) genotype on intrauterine growth of firstborn twin relative to cotwin for offspring of moderate smokers (less than 10 cigarettes per day; white boxes) and offspring of heavy smokers (10 or more cigarettes per day; gray boxes). Intrauterine growth is adjusted for gestational age and twin sex.

Discussion

Maternal smoking during pregnancy is known to retard fetal growth and increase the incidence of low birth weight. The relations between maternal smoking, fetal genotype, and fetal growth were investigated in a large population sample of DZ twins. Maternal smoking retarded growth by 118 g in twins born to mothers who reported smoking less than 10 cigarettes per day, allowing for the effects of twin sex and gestational age, and by 185 g in twins born to heavier smokers. A subsample of 497 twin pairs whose mothers smoked during pregnancy were selected for a molecular genetic study. In this subsample, a functional SNP in the *NQO1* gene (Pro187Ser; rs1800566) was significantly associated with fetal growth within families assuming a dose-related model of effects ($p = .0028$). Post hoc testing within families suggested that possession of the fetal Ser allele protected against fetal growth retardation in the offspring of moderate smokers but not heavy smokers (interaction $p = .047$). These results provide the first demonstration that fetal genotype for a xenobiotic metabolizing enzyme influences IUG under conditions of smoke exposure independently of maternal genotype. This finding implicates the importance to fetal development of Phase I activation of smoke xenobiotics by *NQO1* by cells in the growing fetus or fetal cells in the placenta.

The *NQO1* Pro187Ser variant results from a C to T substitution in exon 6 that codes for a proline to serine change at position 187 in the amino acid sequence. The mutant form of the protein has reduced enzymatic activity (Traver et al., 1997) and is rapidly degraded (Siegel et al., 2001). There is a gene–dose relation between the mutant allele and levels of *NQO1* protein in vivo (Siegel, McGuinness, Winski, & Ross, 1999) and *NQO1* activity in cancer cell lines (Ross & Siegel, 2004): In homozygotes the protein is virtually absent, whereas heterozygotes have intermediate levels of protein concentration and enzymatic activity.

NQO1 is a xenobiotic metabolizing enzyme that catalyzes both Phase I (activation) and Phase II (detoxification) reactions with certain chemicals in tobacco smoke and plays a role in stabilizing an enzyme (p53) that protects against cancer (Ross & Siegel, 2004). The Ser allele may protect against the effects of smoking during pregnancy because the inactive form of the *NQO1* protein produced by Ser heterozygotes and homozygotes does not activate toxic compounds causing DNA damage or oxidative stress (De Flora, Bennicelli, Dagostini, Izzotti, & Camoirano, 1994; Hajos & Winston, 1991; Knox et al., 1988). The protective effects of the Ser allele may be offset by decreased participation in phase II reactions, in which *NQO1* prevents oxidative stress by helping detoxify reactive intermediates (Cadenas, 1995).

The effects of *NQO1* on IUG may differ in moderate and heavy smokers because the metabolism of tobacco smoke is affected by factors such as duration, dose, and timing of exposure (Melikian, Djordjevic, Chen, Richie, & Stellman, 2007). Higher doses or more frequent exposure may alter the balance between the participation of *NQO1* in activation versus detoxification reactions, which likely determines its net contribution to cellular toxicity. The apparent protective effect that was observed for the low-activity Ser allele suggests that at moderate cigarette exposure, the effects of fetal *NQO1* on IUG predominantly reflect its catalysis of Phase I reactions rather than Phase II reactions. The loss of the protective effect in the offspring of heavy smokers might be biochemically explained by a dose-related change in the catalytic activity of *NQO1* toward greater participation in detoxification reactions (Xu et al., 2001). This pattern of results, which has been observed in several studies of cancer epidemiology, conforms to a theory of disease susceptibility that proposes that genetic factors are more important in individuals with moderate smoke exposure than in heavily exposed individuals for whom the environmental risk is overwhelming (Vineis, 2002). However, the authors are conscious of the challenges in interpreting their epidemiological findings in mechanistic terms. Additional exploration in vitro will be necessary to elucidate the functional relation between dose and frequency of exposure and xenobiotic metabolism.

Both the direction of this result and the implied mechanism are consistent with evidence from a Japanese sample that found a protective effect of the maternal Ser allele against the effects of smoking to retard fetal growth (Sasaki et al., 2008). In this study of Japanese families, children born to mothers possessing one or more *NQO1* Ser alleles and who smoked during pregnancy did not suffer significantly lower birth weight than children born to nonsmoking mothers of the same genotype. In contrast, children whose mothers were homozygous for the wild type Pro allele and smoked during pregnancy were born on average 199 g lighter than children whose mothers were homozygous for the Pro allele and who did not smoke during pregnancy (interaction $p < .05$). In addition to its likely interactive effects with tobacco smoke exposure on fetal growth, the Ser allele has been found to protect against respiratory distress in response to airborne pollutants (Bergamaschi et al., 2001; Corradi et al., 2002; David et al., 2003; Millstein, Conti, Gilliland, & Gauderman, 2006).

These studies provide convergent evidence for the importance for developmental and health outcomes of the role of *NQO1* in metabolizing toxic pollutants. However, the magnitude and direction of the association may differ depending on the specific exposure, disease, and population under study. For example, homozygotes for the variant allele are at *increased* risk of bone marrow toxicity after benzene exposure (Nebert, Roe, Vandale, Bingham, & Oakley, 2002). Furthermore, the effects of the *NQO1* Pro187Ser allele may differ depending on ethnic background. The variant allele, which is considerably more common in Asian than in Caucasian populations (Ross & Siegel, 2004), is associated with increased risk of cancers of the lung, bladder, and lower intestine in White populations but may be associated with reduced risk of lung cancer in Asian populations (Chao, Zhang, Berthiller, Boffetta, & Hashibe, 2006; Kiyohara, Yoshimasu, Takayama, & Nakanishi, 2005). The elevation in risk of lung cancer associated with the *NQO1* Ser allele in Caucasians may be further moderated by tobacco use (Chao et al., 2006).

Xenobiotic metabolism by fetal cells may moderate the strength of association between intrauterine smoke exposure and other childhood cognitive and behavioral outcomes, especially those that are robustly associated with low birth weight (for reviews, see Breslau, 1995; Bhutta, Cleves, Casey, Cradock, & Anand, 2002). However, the evidence for a causal relation between maternal smoking during pregnancy and children's cognitive and behavioral outcomes is equivocal (D'Onofrio et al., 2008).

Genetic differences within twin pairs were associated with differences in fetal growth among twins who were exposed to tobacco in utero. Testing for the effects of fetal genotype within families avoids many potential confounds, including gestational and familial effects. In particular, the research design obviates the confound between fetal genotype and maternal genotype, circumvents the effects of maternal smoking on gestational age, and is robust to population stratification. However, the circumstances of gestation and birth are substantially different for twins than for singletons, who account for around 99% of live births. Twins have shorter gestations and lower birth weight than singletons. Using a measure of fetal growth corrected for gestational age may increase the likelihood that the results will generalize to singletons (Morley, 2005). Although the shorter gestation and crowding in the uterus restrict fetal growth in twins relative to singletons, this restriction of range should make it harder rather than easier to detect differences in fetal growth due to maternal smoking or fetal genotype.

Although well suited to testing hypotheses about the effects of fetal genotype within families, the current study loses scope by not genotyping the parents. The maternal genotype directly influences perinatal outcomes over and above its contribution to the fetal genome, as has been demonstrated by the greater risk ratio for being born SGA associated with a family history of SGA in the maternal line than in the paternal line (Svensson, Pawitan, Cnattingius, Reilly, & Lichtenstein, 2006). The current study has tested marginal associations between fetal genotype and IUG, but there may also be interactive effects between maternal genotype and fetal genotype on IUG. In addition, genotyping both parents in addition to the children would allow us to test hypotheses about parent-of-origin effects relating to the fetal genotype (Infante-Rivard & Weinberg, 2005).

The measures of infant birth weight, gestational age, and maternal smoking were obtained by retrospective self-report. More than a dozen studies have assessed the validity of maternally reported birth weight (reviewed in Adegboye & Heitmann, 2008; Lucia, Luo, Gardiner, Paneth, & Breslau, 2006). In these studies from diverse populations, the correlations between maternal reports and documentary records of birth weight range from 0.85 to 0.98 (Lucia et al., 2006). These studies therefore suggest that between 0.85 and 0.98 of the variability in parental reports is shared with documented birth weight. The largest sample compared parentally reported birth weight to birth certificates for over 46,000 children and found that 89% of reported birth weights were accurate to within 29 g (Gayle, Yip, Frank, Nieburg, & Binkin, 1988). The proportion of accurately recalled birth weights was the same for children aged 1 year or older as for younger children. A more recent sample of more than 11,000 British children aged around 9 months reported recall accuracy of 82% within 30 g and 92% within 100 g of the registered birth weight (Tate, Dezateux, Cole, & Davidson, 2005). Given that birth weight differences between smoking and nonsmoking groups in the sample and within-twin pairs were well over 100 g, the authors believe that the effects of inaccurate parental recall of birth weight are likely to be small in comparison with the effects of smoking and genotype that are reported here. Gestational age is also generally accurately recalled by mothers, although the research base is smaller (Adegboye & Heitmann, 2008). In the current study, the results of the analyses within families are in any case unaffected by inaccurate measurement of gestational age.

Maternal smoking was also measured by retrospective self-report. It is likely that pregnant women underreport tobacco use, although accurate measures of tobacco intake can be obtained by these means (Kesmodel & Olsen, 1999). In the current study, dose-related decreases in birth weight provide evidence of the validity of both the measure of tobacco intake and the measure of birth weight. The possibility that inaccurate recall may have contributed to variability in both variables, leading to underestimation of the true effect sizes, cannot be ruled out. There is, in addition, some doubt as to whether retrospective self-reports can accurately assess the timing of smoking cessation among mothers who claimed not to have smoked throughout their pregnancy (Heath et al., 2003). Although the authors are conscious of the importance of questions concerning when mothers smoked during pregnancy in relation to perinatal risk, they believe that the current data set does not provide an adequate basis for addressing these issues.

No significant associations were found between fetal polymorphisms in the folate pathways and IUG. The investigation of the relation between folate genotype and fetal growth, however, lacked information on maternal diet during pregnancy. Although this would not confound the genetic association with IUG within families, it is possible that the effects of genetic association are strongest in families in which maternal intake of folic acid is low (Nurk et al., 2004). If true, this possibility would reduce the power of this investigation to detect the effects of folate pathway genes on IUG. It is likely that mothers with low folate intake were represented in this sample because of the absence of mandatory folic acid supplementation in the United Kingdom. The authors therefore believe that these negative results do provide some evidence against the influence of fetal polymorphisms in the folate pathway on IUG, consistent with previous investigations of fetal *MTHFR* and *SHMT1* genotype (Glanville et al., 2006; Infante-Rivard et al., 2002; Relton, Pearce, Burn, et al., 2005) but *contra* a marginally significant report of association between fetal A66G *MTRR* (rs1801394) genotype and growth restriction in babies born at term (Glanville et al., 2003).

Finally, the genetic variants that were studied may moderate the risk of environmental exposures other than smoking that potentially also affect birth weight, such as diesel exhaust exposure and folate intake. A priority in this sample, therefore, will be to conduct further genotyping in twins whose mothers did not smoke during pregnancy, in order to allow conventional testing of a hypothesis of gene–environment interaction. Future epidemiological research should investigate the replicability of this result in other populations and in singletons, the influence of maternal genotype, the possibility of Gene × Gene interactions (i.e., epistasis), and imprinting.

Prenatal Antecedents of Newborn Neurological Maturation

Janet A. DiPietro, Katie T. Kivlighan, Kathleen A. Costigan, Suzanne E. Rubin,
Dorothy E. Shiffler, Janice L. Henderson, and Joseph P. Pillion
Johns Hopkins University

Fetal neurobehavioral development was modeled longitudinally using data collected at weekly intervals from 24 to 38 weeks gestation in a sample of 112 healthy pregnancies. Predictive associations between 3 measures of fetal neurobehavioral functioning and their developmental trajectories to neurological maturation in the first weeks after birth were examined. Prenatal measures included fetal heart rate (FHR) variability, fetal movement, and coupling between fetal motor activity and heart rate patterning; neonatal outcomes include a standard neurologic examination (n = 97) and brainstem auditory evoked potential (BAEP; n = 47). Optimality in newborn motor activity and reflexes was predicted by fetal motor activity, FHR variability, and somatic–cardiac coupling predicted BAEP parameters. Maternal pregnancy-specific psychological stress was associated with accelerated neurologic maturation.

> If we pursue our quest beyond the newborn period, we find ourselves suddenly in an entirely new situation, where our organism is not seen, nor scarcely felt nor heard. Our environmental situation has become, if not at once more complex, at least to be likened to the postnatal environment only with great difficulty. (Sontag & Richards, 1938, p. 1)

While the last decade has been marked by increasing appreciation of the role of the prenatal environment in providing the substrate for postnatal health and development, recognition of the continuous nature of human development from conception was evident in the earliest publications of the Fels Research Institute, established in 1929. Since that time, many of the core interests of developmental psychology concerning development and expression of individual differences and the moderating role of early environmental influences have begun to converge with epidemiologic methodology. The construct of ''fetal programming'' has been applied broadly to represent discoveries of prenatal influences on postnatal functioning, typically in adulthood (Barker, 2006; O'Brien, Wheeler, & Barker, 1999; Young, 2002). Although this approach has generated an enormous body of data, thereby sparking great interest in the prenatal period, most studies rely on readily available data sources, such as birth weight, that provide only vague proxy for the gestational environment and can offer little information about mechanisms mediating observed associations.

A second, more direct, approach is to measure function during the prenatal period to evaluate its role as the foundation for postnatal function. This permits measurement of a single construct and allows determination of how early experiences or exposures might affect the latter via their influence on the former. Technological advances available only after the dissolution of the Fels Institute have made clear that by the end of gestation developmental parameters that are measured extensively in the neonate and infant, and are integral to theories of development, originate at neither term nor with birth (Als, 1982; Prechtl, 1984). The view that fetal neurobehaviors reflect neurological development has been supported by studies conducted in healthy populations (Amiel-Tison, Gosselin, & Kurjak, 2006; DiPietro, Irizarry, Hawkins, Costigan,

---

This research was supported by NIH/NICHD Grant R01 HD27592 to the first author. Newborn evoked potential data collection was supported by a research grant equipment loan from Intelligent Hearing Systems, Miami, FL. We thank Rafael Irizarry, Department of Biostatistics, for his contribution to the original design of the fetal protocol, and Kristen Byrnes, for her assistance with Dubowitz training and administration. We remain indebted to the diligent and generous support of our study families, without which this work would not be possible.

& Pressman, 2001; Hepper, 1995; Krasnegor et al., 1998; Nijhuis & ten Hof, 1999; Sandman, Wadhwa, Hetrick, Porto, & Peeke, 1997). Further support is provided by observations of differences in neurobehavioral functioning in fetuses afflicted by congenital anomalies related to the nervous system (Hepper & Shahidullah, 1992; Horimoto et al., 1993; Maeda et al., 2006; Romanini & Rizzo, 1995); exposure to deleterious antenatal conditions that affect development, including growth restriction (Nijhuis et al., 2000) and maternal diabetes (Kainer, Prechtl, Engele, & Einspieler, 1997); and exposure to potentially neurotoxic substances (Gingras & O'Donnell, 1998; Mulder, Morssink, van der Schee, & Visser, 1998). The first aim of this study was to evaluate the association between central nervous system maturation in the fetus, as indicated by fetal neurobehavioral development, and neurologic functioning of the newborn infant in an effort to identify early indicators of optimal function.

While we have examined a number of fetal neurobehavioral parameters in past cohorts, three were selected for this analysis based on conceptual considerations regarding relevance to postnatal neurological functioning. The first parameter is spontaneous variability in fetal heart rate (FHR). Measurement of phasic or nonphasic cardiac variability has had a distinguished history in developmental science as a marker of the physiological regulation that corresponds to infant and child performance and behavior. Variability in FHR is among the most prominently accessible features of the fetus, and is central to clinical antepartum assessment as an indicator of the developing balance between parasympathetic and sympathetic innervation (Freeman, Garite, & Nageotte, 1991). Recently, FHR variability at or after 28 weeks gestation and steeper developmental trajectories were shown to be significantly associated with mental, psychomotor, and language development in the 3rd year of life (DiPietro, Bornstein, Hahn, Costigan, & Achy-Brou, 2007). Significant stability within individual fetuses during gestation was also demonstrated (DiPietro et al., 2007).

Motor activity is the second prenatal parameter, selected for its conspicuous nature as an individual difference in both the fetus and child (Eaton, McKeen, & Campbell, 2001). A few studies on small samples have suggested conservation of very specific attributes of fetal motor patterning between the fetus and infant (Almli, Ball, & Wheeler, 2001; Groome et al., 1999). Fetal motor activity is significantly associated with activity levels in early childhood for boys, and predictive of a range of regulatory temperament characteristics (DiPietro et al., 2002). The putative assumption is that fetal motor activity prepares the neurologic circuitry and musculature for postnatal function (Prechtl, 1984). Data generated from animal models further reveal that variation in fetal motor behavior reflects ontogenic adaptation to the intrauterine environment, which in turn fosters subsequent maturation (Smotherman & Robinson, 1987).

The third fetal parameter combines FHR and motor activity into a single measure reflecting the degree of covariation between the two. Observation of synchrony between acceleration in heart rate and motor activity in fetuses is long-standing (Sontag & Richards, 1938). Since then, cardiac–somatic coupling has become implicated as a function of parasympathetic control, which becomes the increasingly prominent influence as gestation advances. The association between movement and heart rate in the fetus has been most often attributed to centrally mediated coactivation of cardiac and somatomotor processes (Johnson, Besinger, Thomas, Strobino, & Niebyl, 1992; Timor-Tritsch, Dierker, Zador, Hertz, & Rosen, 1978; Vintzileos, Campbell, & Nochinson, 1986). Documentation of normative development of this association in several longitudinal samples reveals a predictable progression during gestation marked by increased levels of correspondence and diminished latency between parameters (DiPietro, Hodgson, Costigan, Hilton, & Johnson, 1996; DiPietro et al., 2001; DiPietro et al., 2004).

One of the most frequently investigated sources of maternal environmental variation on the developing fetus has been maternal psychological distress. Most studies examine effects on pregnancy outcomes (i.e., birth weight and gestational age). Although a number have reported significant associations between maternal stress and/or anxiety during pregnancy and shortened gestation or restricted growth, results are not uniform (Alder, Fink, Bitzer, Hosli, & Holzgreve, 2007; Littleton, Breitkopf, & Berenson, 2007). Fewer studies link maternal distress to observed child or infant outcomes; of those that do, most examine consequences on attentional or behavioral regulation (Davis et al., 2004; Gutteling et al., 2005; Huizink, Robles de Medina, Mulder, Visser, & Buitelaar, 2002; Van den Bergh et al., 2005). Examination of child performance on standardized assessments has yielded conflicting results. For example, two studies report deleterious effects between maternal psychological stress and/or anxiety on Bayley Scales of Infant Development (Buitelaar, Huizink, Mulder, Robles de Medina, & Visser, 2003; Laplante et al.,

2004) whereas another reports that maternal psychological distress accelerates development (DiPietro, Novak, Costigan, Atella, & Reusing, 2006). The handful of studies examining the most proximal associations, those between maternal psychological distress and fetal functional activity, are neither consistent nor conclusive. The second aim of this study was to systematically examine the contribution of maternal nonspecific anxiety levels and pregnancy-specific stress on both fetal and neonatal maturation. Boys have typically been observed to be more vulnerable to prenatal exposures in human studies, and a potential mechanism specific to prenatal stress has recently been uncovered in rodent models (Mueller & Bale, 2008). Thus, potential sex differences in any observed associations will be examined.

Growth and development during gestation both reflect maturative processes. Growth is generally defined as an increase in cell mass or number, whereas development refers to differentiation of function. Although growth is relatively straightforward to measure at birth in terms of size, there are a variety of ways that functional maturation may be expressed and measured. As our focus is on neurologic maturation, we selected two different indicators of neurologic function. The first is a traditional neurological examination of the newborn. Assessments of this type originated in the 1960s and contain a fairly standard repertoire of neonatal characteristics, including tone, posture, primitive reflexes, and behavior. The Dubowitz Neurological Exam (Dubowitz, Mercuri, & Dubowitz, 1998), used in this study, was selected because scoring has been validated around the construct of "optimality" such that the exam distinguishes the optimal point along dimensions in which suboptimal performance occupies each end (e.g., hyporesponsivity through hyperresponsivity). However, despite their widespread use, assessments of this type have a number of limitations, including restriction to features of neonatal functioning that can be observed and/or manipulated and fairly subjective scoring based on "stick figure" drawings of response ranges.

As a result, a second approach was included on a subset of infants using measurement of brainstem auditory evoked potentials (BAEPs) as a more objective and precise indicator of neurological maturation. BAEPs have standard clinical application in the newborn period in evaluation of audition. A growing literature has indicated that they are effective in serving as a marker for more general neural maturation. Variation in BAEP parameters has been linked to prenatal lead exposure (Rothenberg, Poblano, & Schnaas, 2000), prenatal exposure to potentially neurotoxic therapeutic drugs (Poblano et al., 2003), transient depression of Apgar scores (Jiang, Xu, Brosi, Shao, & Wilkinson, 2007), iron deficiency anemia (Roncagliolo, Garrido, Walter, Peirano, & Lozoff, 1998), and breast-feeding and formula fortification (Khedr, Farghaly, El-DinAmry, & Osman, 2004; Unay et al., 2004). These results suggest that BAEP may serve as a marker for functional integrity of the nervous system beyond the specific pathway of conduction.

The BAEP consists of a series of three major peaks or waves (i.e., I, III, and V) that are generated in the eighth cranial nerve and brainstem. The neural generators for Waves I and III in humans are the auditory nerve and cochlear nucleus, respectively. The generator for the most positive peak of Wave V is the termination of the fiber tract of the lateral lemniscus, whereas the following negative trough is produced by slow dendritic potentials in the inferior colliculus (Moller & Jannetta, 1982). BAEP responsivity can be detected in some preterm infants as early as 26 weeks gestation but is not typically measurable until 30–32 weeks postconceptional age (Rotteveel, de Graaf, Colon, Stegeman, & Visco, 1987). The absolute latencies of Waves I, III, and V as well as the interpeak latency intervals progressively decrease over the course of development (Amin, Orlando, Dalzell, Merle, & Guillet, 1999). In full-term infants, the BAEP undergoes rapid changes in the first 4 days of life, with the most rapid changes occurring in the first 24 hr (Yamasaki et al., 1991). The later components (i.e., Waves III and V) undergo more marked changes in latency than the most peripheral component due to the earlier maturation of the peripheral nervous system relative to the later maturing central auditory pathways (Montandon, Cao, Engel, & Grajew, 1979). The prolonged latencies in the BAEP in neonates reflect incomplete neural myelination of the fibers in the auditory pathway, reduced axon diameter, and immaturity in synaptic function (Eggermont & Salamy, 1988; Folsom & Wynne, 1987).

Based on the constructs underlying each dependent and independent measure, we expect the following: (a) fetal motor activity will be most predictive of newborn performance on the standard neurological examination, given the focus on postnatal tone, posture, and motor behavior; (b) fetal measures more closely reflective of neural functioning (i.e., cardiac variability and somatic-cardiac coupling) will be most predictive of event-related potentials (BAEP); and (c) maternal psychological distress will accelerate fetal neurobehavioral development and neonatal neurological functioning.

Method

Participants

Participants were 112 self-referred normotensive, nonsmoking women with normally progressing pregnancies carrying singleton fetuses. Accurate dating of the pregnancy, based on early first trimester pregnancy testing or examination and generally confirmed by early ultrasound was required (*M* gestational age at pregnancy detection = 4.8 weeks; *SD* = 1.2). The sample represents a relatively stable population of well educated (*M* years education = 17.2 years, *SD* = 2.1), mature (*M* age = 31.2, *SD* = 4.6), and married (91%) women. Most were non-Hispanic White (79.5%); the remainder were African American (13.4%), or Hispanic or Asian (7.1%). Fifty-seven (51%) of the fetuses were female.

Procedure

Prenatal. To fully represent the gestational age span from 24 to 38 weeks gestation, participants were stratified into three cohorts with staggered entry into the protocol between 24 and 26 weeks gestation and tested in 3-week intervals. That is, data collection for the first cohort proceeded at 24, 27, 30, 33, and 36 weeks; the second at 25, 28, 31, 34, and 37 weeks; and the third at 26, 29, 32, 35, and 38 weeks. Prenatal visits were scheduled at 13:00 or 15:00. On the day of the visit, women were instructed to eat 1.5 hr prior to the visit but not thereafter. Self-report psychosocial questionnaires were completed upon arrival at the laboratory at each visit. A brief ultrasound scan was administered to determine fetal position followed by 50 min of undisturbed fetal recording.

The psychosocial questionnaires included measures of general anxiety and pregnancy-specific stress, both administered at each visit. The former was evaluated by the Spielberger Trait Anxiety Scales (Y-2; STAI; Spielberger, 1983), one of the most commonly used and extensively validated self-administered measures of anxiety. This questionnaire includes twenty 4-point items; items were reversed as necessary and summed such that higher scores indicate greater trait anxiety. Pregnancy-specific stress was assessed by a shortened form of the Pregnancy Experiences Scale (PES). The original version was previously validated (DiPietro, Ghera, Costigan, & Hawkins, 2004) and contains 41 items specific to pregnancy, each rated on 4-point scales and scored in terms of intensity and frequency. The revised version was developed for the recurring and frequent administration of the current design. The PES–Brief includes the 10 most frequently endorsed hassles and uplifts from the full PES, each rated on the original 4-point scale, and averaged. Higher values reflect greater perceived intensity of either negative or positive stressors during pregnancy. Comparable reliability and stability to the original have been demonstrated (DiPietro, Christensen, & Costigan, 2008).

Fetal data were collected using a Toitu (MT320) fetal actocardiograph (Toitu Co., Ltd, Tokyo, Japan). This monitor detects fetal movement (FM) and FHR with a single wide array transabdominal Doppler transducer and processes this signal through a series of autocorrelation techniques. The actograph detects FM by preserving the remaining signal after bandpassing frequency components of the Doppler signal that are associated with FHR and maternal somatic activity. Reliability studies comparing actograph based versus ultrasound visualized FM have found the performance of this monitor to be highly accurate in detecting both fetal motor activity and quiescence (Besinger & Johnson, 1989; DiPietro, Costigan, & Pressman, 1999; Maeda, Tatsumura, & Utsu, 1999).

Fetal data were digitized and analyzed off-line using software developed in our laboratory (GESTATE; James Long Company, Caroga Lake, NY). Fetal heart rate data underwent error rejection procedures based on moving averages of acceptable values as needed. Variable extraction included FHR variability (standard deviation of each 1-min epoch of FHR averaged over the full recording). Fetal movement data represent raw voltage values generated from the actograph calibrated by multiplying by a conversion factor and scaled from 0 to 100 in arbitrary units (a.u.s). Fetal motor activity was computed as the mean signal values generated per minute, averaged over the entire recording. The relation between FHR and motor activity (hereafter, FM–FHR coupling), was calculated as the proportion of discrete FM bouts, defined as commencing when an actograph signal attained an amplitude of 15 units and ending with a cessation of signal for at least 10 s, that were associated with excursions in FHR ≥ 5 bpm over baseline within 5 s before the start of a movement or within 15 s after the start of a movement, consistent with previously developed criteria (Baser, Johnson, & Paine, 1992; DiPietro et al., 1996).

Postnatal. Infants were examined using the Dubowitz Neurological Examination of the Newborn (Dubowitz et al., 1998) within the first 2 weeks after birth during a home visit conducted by a pediatric nurse practitioner. The assessment is a more intensive version of exams routinely used to assess status and gestational age immediately postpartum. It contains 34 items distributed into six clusters: Tone (e.g., posture and head control), Tone Patterns (e.g., extensor vs. flexor), Reflexes (e.g., Moro, placing), Motor (e.g., spontaneous movements and head raising), Abnormal Signs (e.g., tremoring), and Behavior (e.g., orientation, irritability). Scoring proceeded based on optimality criteria, developed by validation across gestational age (Dubowitz et al., 1998). That is, raw scores are coded along an optimality continuum such that a higher score on an item is not necessarily coded as more optimal.

A second visit was scheduled to collect BAEP. Initially, the protocol was designed to accomplish both at one visit; however, this interfered with obtaining BAEP data of sufficient quality. A licensed audiologist was subsequently dispatched to conduct a second visit but this change was not implemented until the 21st participant. BAEP measurements were undertaken utilizing single-channel differential recording with an active electrode attached to the high forehead and a reference electrode attached to the mastoid. The contralateral electrode served as ground. Testing relied on a portable BAEP unit (Smart USB Lite; Intelligent Hearing Systems, Miami, FL) connected to a laptop computer through a USB port to a single channel amplifier. Infants were generally swaddled and placed in a supine position or in their mothers' arms. Recording took place while infants were in a sleep state. Stimuli were rarefaction clicks presented at a rate of 27.7/s through ER3 insert phones at a level of 70 dB nHL. Responses to two trials of 2,048 clicks were filtered (30–1500 Hz) and amplified (100 K). A 12-ms recording window was utilized. The analysis was undertaken offline (SmartEP System, version 3.82; Intelligent Hearing Systems) and latencies for Waves I, III, and V were assessed for each trial and each ear. Both trials were averaged. No significant differences in values generated between right and left ears were detected, so these were further averaged. Interpeak latency intervals were computed by subtracting the earlier wave from the later. The following variables were used in the analysis: Wave V latency (i.e., stimulus presentation to Wave V peak) and interpeak intervals I–III, III–V, and I–V.

Analysis Plan

Variables were examined for skewness and outliers. Hierarchical linear models (HLMs) were estimated using SPSS Mixed (version 15.0) to examine growth in fetal neurobehavioral development across the second half of gestation. Models incorporated two levels: Level 1 models the change in the dependent variable over time for each individual in the sample, whereas Level 2 relates individual growth parameters to predictors of interest (Bryk & Raudenbush, 1987; Singer & Willett, 2003). Two advantages emerge from this approach. First, individuals are not directly compared based on the dependent variables of interest but on the parameters describing their developmental slope across gestation. Therefore, week of gestation at observation was allowed to vary across participants and is accounted for in the Level 1 model. Second, the number of data points per subject can also vary as long as there is sufficient information to describe the developmental trajectory for that individual. Unbalanced data sets, including those with planned missing data as generated by the current design, are thus acceptable in these models (Singer & Willett, 2003).

Restricted maximum likelihood was used in reporting model parameters when assessing the significance of the random effects; degrees of freedom were estimated using the Satterthwaite method. The 95% confidence interval (CI) for random variation around each fixed effect was calculated as ± 2 *SD* of its accompanying random variance term. To best describe growth trajectories, linear, polynomial, and piecewise (spline) terms were examined during model fitting. Models were centered at 38 weeks, such that the intercept represented individual differences in fetal neurobehaviors (FHR variability, motor activity, and FM–FHR coupling) at the end of gestation. Models were initially specified with random intercepts, and the effects of including random slopes on model fit were subsequently evaluated. The fixed effects of each predictor (e.g., fetal sex, maternal distress) on the intercept and change across gestation, calculated as slope from 24 to 38 weeks, were tested sequentially in the whole group. Model fit was assessed with likelihood deviance difference tests for nested models (Singer & Willett, 2003). This process evaluates the significance of the change in model fit following the addition of a new parameter(s) (e.g., a quadratic term) to a previously tested model (e.g., a linear model).

Exploratory analyses were used to identify potential covariates. No outliers in postnatal measures were detected. Random intercepts and slopes exported from the HLM models described above were used in correlation and regression analyses.

Pearson correlations were computed between fetal and infant measures. Regression models were constructed by entering covariates at the initial step (e.g., gestational age) followed by entry of the fetal predictor (i.e., intercept or slope for FHR variability, FM–FHR coupling, and fetal motor activity).

Results

Fetal Neurobehavioral Development From 24 to 38 Weeks Gestation

Nearly half (49.1%) of the participants completed all five data visits, 38.4% completed four visits, and 12.5% completed three visits. Of those with missed visits, 13 (22.8%) were a result of delivery of infant prior to the last (i.e., 36–38 weeks) scheduled visit. Scheduling problems associated with the assessment schedule of 3-week intervals were the most common reason for the remaining missed visits. HLMs were fit to produce estimates of individual differences in fetal neurobehaviors at 38 weeks (intercept) and growth across the second half of gestation. Model parameters are given in Table 1. Unadjusted raw means, best fit models, and CIs based on individual values are presented in Figure 1. No sex differences in intercept or developmental slope were detected for fetal measures.

Fetal heart rate variability. Fetal heart rate variability increased linearly from 24 to 38 weeks gestation ($p < .001$) by 0.27 bpm (4.5%) per week (95% CI: 0.22–0.31) without any significant changes in slope (Figure 1a), to reach an average of 9.95 bpm by 38 weeks (95% CI: 9.44–10.47).

Fetal motor activity. Ten visits were excluded for fetal motor activity due to technical difficulties with the FM signal and an additional motor activity outlier (+3 *SD*) was removed at 33 weeks. The amplitude of fetal motor activity increased gradually at a rate of 0.04 a.u.s. (0.7%) per week (95% CI: 0.01–0.07) with advancing gestation ($p < .05$; Figure 1b). By 38 weeks, mean fetal motor activity reached a level of 5.66 a.u.s. (95% CI: 5.37–5.95 a.u.s.).

FM–FHR coupling. A single outlier (+3 *SD*) was excluded from the FM–FHR coupling analysis at 34 weeks. FM–FHR coupling increased steadily from 24 to 32 weeks gestation ($p < .001$), with a significant decline in slope after 32 weeks (32-week spline term, $p < .01$; Figure 1c). The coupling index initially increased at a rate of 0.014 (8.0%) per week of gestation (95% CI: 0.011–0.017). After 32 weeks, the rate of increase declined by 0.010 per week (95% CI: −0.003 to −0.017) to 29% of the original slope. By 38 weeks, the mean FM–FHR coupling index had reached 0.309 (95% CI: 0.287–0.330).

Random linear slopes improved the fit for FHR variability, motor activity, and FM–FHR coupling models (*p*s < .05). Additional piecewise models were generated for FM–FHR coupling to obtain individual differences in linear slopes before and after 32 weeks.

Postnatal Assessment

Infant data, stratified by sex, are presented in Table 2. Infants were normally grown and none were low birth weight. There were four instances of mildly preterm delivery (two each at 35 and 36 weeks gestation); all were discharged from the

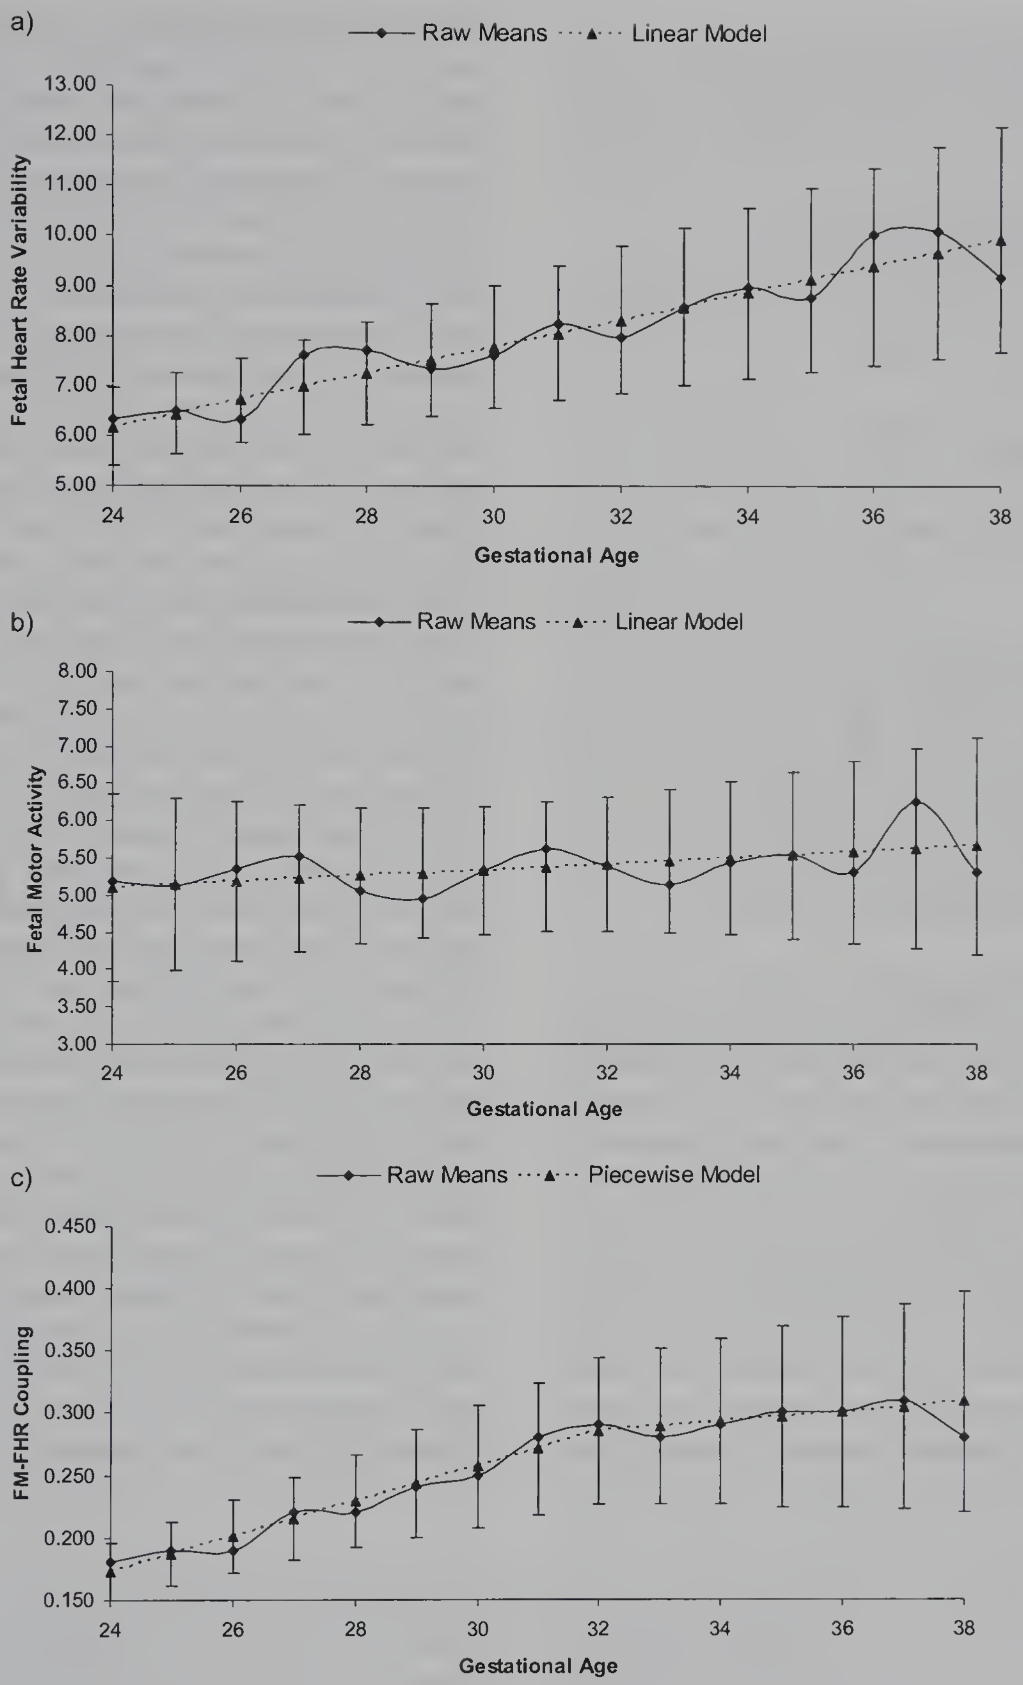

Figure 1. Raw means and best fit models with 95% confidence intervals based on individual values for fetal neurobehaviors across the second half of gestation. Fetal heart rate variability (a) and motor activity (b) increased linearly from 24 to 38 weeks gestation. Fetal heart rate–movement coupling (c) increased from 24 to 32 weeks, followed by a decline in rate after 32 weeks.

hospital on routine schedules. Twenty-four percent (n = 27) were delivered by Caesarian section. Six infants were determined to be too sick to visit and test (e.g., thrombocytopenia, sepsis) during the evaluation period. There were no sex differences on birth outcome measures.

Dubowitz Neurological Exam. Ninety-seven of the remaining 106 newborns received the Dubowitz Neurological Exam during the home visit (91.5%). Reasons for lack of visiting included nurse unavailability (n = 5), residence relocation out of local area (n = 2), or declining of evaluation (n = 2). Infants

were examined between Days 2 and 9 postpartum ($M = 5.0$, $SD = 1.2$); 78% were tested on Day 4, 5, or 6. There were no significant, or near significant correlations between age at test and any optimality cluster, rs(95) range from −.10 to .06. One of the six optimality cluster scores (i.e., Abnormal Signs) did not have sufficient variability to analyze so was discarded. Remaining cluster values are presented in Table 2; there were no sex differences.

Fetal motor activity level was positively associated with optimality in the Motor and Reflex clusters, $r = .27$, $p < .01$, and $r = .20$, $p < .05$, respectively. Exploratory analysis revealed that a number of birth characteristics were also associated with some of the exam clusters, including gestational age and delivery type (vaginal vs. Caesarian). In general, infants with longer gestations scored more optimally whereas those delivered by Caesarian section scored less optimally. Regression results, controlling for gestational age, delivery type, and infant sex are presented in Table 3. In general, more active fetuses displayed more optimal motor and reflex patterns as neonates. In addition to level, analysis of associations between the slope of fetal motor activity during gestation indicated positive associations with Motor cluster optimality, $r(95) = .20$, $p < .05$, but the $r^2\Delta$ did not remain significant in the regression model, $F(4, 92) = 3.04$, $p < .10$. However, a significant negative association between Tone Pattern optimality and fetal activity slope was also detected, $r(95) = -.23$, $p < .05$, and contributed additional significant variance to the regression model, multiple $R = .47$, $r^2\Delta = .06$, $F(4, 92) = 6.57$, $p < .01$; there was no association between Tone Pattern and fetal activity level.

The fetal motor measure used in the modeling that generated these gestational values is an indicator of overall motor signal output and does not capture all characteristics of fetal motor behavior. Supplemental correlations were computed between four additional measures of motor behavior generated at the last fetal assessment and the Motor and Reflex optimality scores to determine the generalizability of the motor results. Fetal motor measures were contributed by 86 fetuses at this assessment, of those, 77 had a postnatal exam. Significant associations were detected for three of these measures with postnatal Motor optimality: mean duration of individual movements, the longest movement bout during the recording, and the total time, in minutes, spent moving, rs(75) = .25, ps < .05. The number of movement bouts was unrelated to Motor optimality scores, and no cross-sectional motor characteristics

*$p < .05$. **$p < .01$.

at term, other than the longitudinally modeled measure, were related to Reflex optimality.

Significant, negative associations were detected between the level and developmental slope of FHR variability with Tone Optimality, $rs(95) = -.24$, $ps < .05$. Both level, multiple $R = .32$, $R^2\Delta = .047$, $F(4, 92) = 4.85$, $p < .05$, and slope, multiple $R = .31$, $R^2\Delta = .045$, $F(4, 92) = 4.63$, $p < .05$, contributed significant unique variance to the regressions. FM–FHR coupling intercept and slope were unrelated to Optimality scores.

Brainstem auditory evoked potential. As described in the Procedures subsection, dedicated BAEP visits commenced partway into the protocol. Testing occurred between postpartum Days 3 and 14 ($M = 8.6$, $SD = 2.8$; M interim between first and second visits = 3.5 days, $SD = 2.7$). There were 70 visits in which BAEP data collection was attempted. One parent declined the procedure, and poor signal quality or recording problems (e.g., persistent 60 cycle noise, lack of infant sleep state, motor artifact, or electrical interference from household sources that could not be determined) resulted in inability to collect complete data (i.e., two trials of 2,048 stimuli presentations per ear) at 22 of the visits, resulting in 47 infants with BAEP data. Axillary temperature was recorded for each infant at the start of the visit because of an existing known relation between body temperature and BAEP conductance (Bastuji, Larrea, Bertrand, & Mauguiere, 1988; Litscher, 1995). Infants on whom BAEP data could and could not be collected did not differ on birth characteristics (e.g., birth weight, gestational age, and delivery method), sex, or Dubowitz cluster scores. The only significant difference was postpartum age at which the data collection was attempted: Successful recordings were more likely to be generated on slightly older infants, $M = 9.4$ versus 7.6 days; $t(65) = 2.67$, $p < .01$. Mean values are presented in Table 2.

Gestational age, postnatal age at testing, and measures of size taken at the prior visit were unrelated to BAEP waves, with one modest exception. Greater head circumference was negatively associated with interpeak latency III–V, $r(45) = -.32$, $p < .05$. However, boys showed significantly slower BAEP latencies for Wave V, $t(45) = 3.03$, $p < .01$, and interpeak intervals I–V, $t(45) = 2.93$, $p < .01$ and I–III, $t(45) = 2.81$, $p < .01$. Infants with higher temperatures tended to have longer latencies, rs ranged from .21 to .32 for Wave V and interpeak latencies I–III and I–V, although only the last value attained significance ($p < .05$). Table 4 presents partial correlation coefficients, controlling for temperature, between FHR variability, and FM–FHR coupling intercepts and slopes for each BAEP measure. In general, higher levels and steeper developmental trajectories for FHR variability and FM–FHR coupling were predictive of shorter interpeak intervals from Waves I and III to Wave V. Fetal motor activity was unrelated to BAEP.

Table 4

Partial Correlations Between Fetal Neurobehavioral Measures and BAEP Values Controlling for Infant Temperature (N = 47)

		Interpeak latencies		
	Wave V	I–III	III–V	I–V

Correspondence Between Dubowitz Exam and BAEP Assessment

No association between any cluster score of the Dubowitz neurologic exam and any BAEP variable was detected.

Associations Between Maternal Psychological Distress and Development

Fetal neurobehavioral development. HLMs did not reveal any change over gestation for either pregnancy-specific hassles (estimate = 0.00, $SE = 0.00$, $t = 1.58$, *ns*) or trait anxiety (estimate = 0.02, $SE = 0.04$, $t = 0.61$, *ns*). Pregnancy-specific uplifts gradually increased (estimate = 0.01, $SE = 0.00$, $t = 3.11$, $p < .01$). Variables were centered at the grand mean, and average scores were used in analysis of associations with fetal neurobehavioral measures. Means are as follows: PES intensity of hassles, $M = 1.41$, $SD = 0.39$; PES intensity of uplifts, $M = 2.37$, $SD = 0.41$; and trait anxiety, $M = 31.52$, $SD = 7.13$.

Trait anxiety and pregnancy uplifts were not associated with level or change for any fetal neurobehavior. Because chest wall motions generated by fetal hiccups can generate significant artifact in the motor signal, the presence of fetal hiccups in 59 of the visits was controlled for by inclusion of a dummy variable in these analyses. A greater intensity of pregnancy hassles (1 *SD* above the mean) was predictive of 2.8% higher FHR variability (95% CI: 0.2–5.4), $t = 2.17$, $p < .05$, and marginally higher motor activity (2.5%; 95% CI: −0.0 to 5.2), $t = 1.86$, $p = .065$ in models centered at 38 weeks (Figures 2a and 2b). These associations were confirmed by correlations between these two fetal measures and the mean score for intensity of hassles, $rs(110) = .19$, $ps < .05$. In addition, more intense pregnancy hassles (+1 *SD* above the mean) were also associated with an increase in the slope of FM–FHR coupling after 32 weeks by 0.010 per + 1*SD* per week (95% CI: 0.001–0.019), $t = 2.10$, $p < .05$, augmenting it to twice the post-32-week slope. Conversely, less intense pregnancy hassles (−1 *SD* below the mean) were associated with a decline of 0.010 per 1 *SD* per week, resulting in a nearly flat FM–FHR coupling slope after 32 weeks (i.e., 0.0001 increase per week).

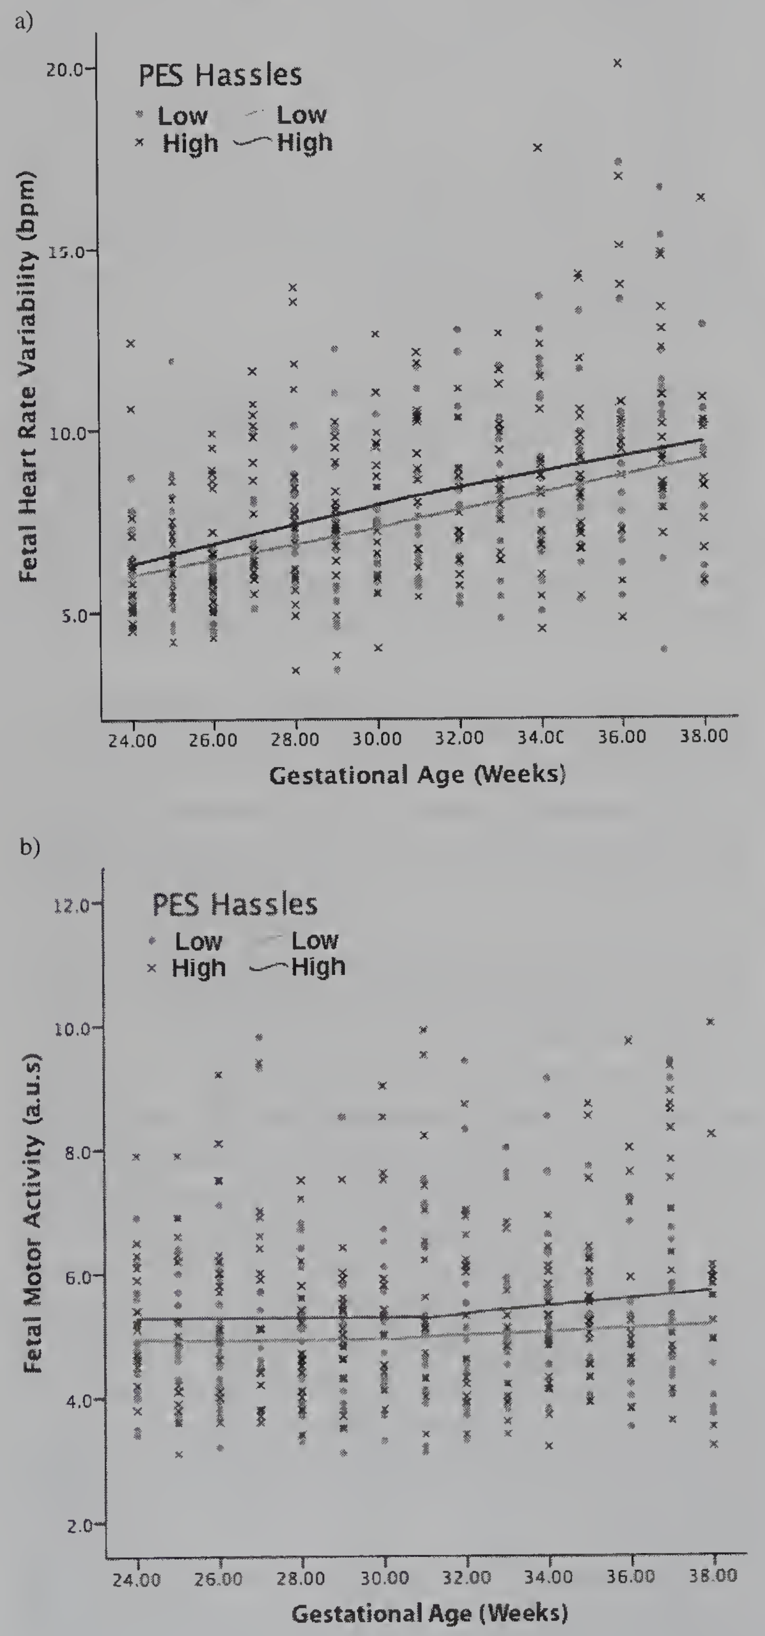

Figure 2. Fetuses of mothers reporting a greater intensity of pregnancy-specific hassles (1 *SD* above the mean; solid black line) show significantly higher heart rate variability (a) and more fetal motor activity (b) during the second half of gestation.

Postnatal maturation. PES–Brief hassles, uplifts, and STAI anxiety scores were unrelated to the motor and tone-related optimality clusters of the Dubowitz exam. However, exploratory data analyses indicated significant associations between PES–Brief hassles intensity and three components of the Behavior optimality cluster: irritability, consolability, and crying, but not with items related to alertness or orientation performance. A composite score for irritability was derived from these three items; the association between it and PES hassles was significant, $r(95) = .28$, $p < .01$. Separate analysis by sex revealed that this association was significant for boys, $r(45) = .45$, $p < .01$, but not for girls, $r(48) = .08$. The coefficients were significantly different, $Z = 1.75$, $p < .05$, one-tailed.

There was a significant pattern of associations between PES–Brief hassle intensity scores and BAEP values as follows: Wave V, $r(45) = -.35$, $p < .05$; interpeak latencies I–III, $r(45) = -.27$, $p < .10$; and interpeak latencies I–V, $r(45) = -.30$, $p < .05$. There were no significant associations for PES–Brief uplifts or STAI anxiety scores. Analyses conducted separately by sex indicated augmentation of these associations for boys, $rs(22)$ ranged from −.35 to −.45. In contrast, none of the associations with PES hassles was significant for girls. However, significant associations emerged for anxiety scores, Wave V and interpeak intervals I–V, III–V, $rs(21)$ ranged from −.48 to −.59.

Discussion

The current study provides confirmation of the three working hypotheses and underscores the role of the fetal period in providing the foundation for postnatal development. The observed patterns of associations were consistent with the prediction that fetal motor activity would be associated with newborn maturation as assessed by a traditional examination but that FHR variability and somatic–cardiac coupling would differentially predict BAEP. With respect to the first of these, the current results support the long-standing speculation that prenatal motor activity is an ontogenic adaptation that prepares the fetus for postnatal life (Prechtl, 1984). There are at least two interpretations of the observed associations. The first is that the relation between greater fetal motor activity and more optimal neonatal motor and reflex performance simply reveals conservation in motor functioning from the prenatal to postnatal periods and reflects an intrinsic characteristic of the individual perhaps as a result of a genetic or other constitutional contribution. The second possibility is that greater fetal motor activity provides a practice effect that develops the musculature and potentiates the neural circuitry associated with more optimal neonatal motor performance and reflex responsivity. Based on psychobiological observations of the epigenetic determination of prenatal motor behavior in animal preparations (Smotherman & Robinson, 1987), it is likely that both interpretations contribute to the observed findings. There was an unexpected negative association between steeper developmental slopes for motor activity and lower newborn Tone Pattern. Examination of the scale scores indicates that lower Tone Pattern scores were generally reflective of hyperresponsivity in flexor or extensor tone. Given that there was no association with fetal motor activity level, this suggests that an unusually steep developmental trajectory of motor activity may reflect an inoptimal developmental progression that results in excess tone. Similarly, we have no ready explanation for the negative associations between FHR variability, a measure that is typically regarded as an indicator of autonomic integration, and Tone optimality.

The second set of findings relates measures of fetal neurobehavioral functioning that have been conceptually linked to maturation of the nervous system with measurement of neural conductivity. Higher levels and steeper slopes of both FHR variability and FM–FHR coupling during development were associated with shorter neural conduction times for Wave V latency in general as well as the Wave III–V interpeak interval. The intervals between the component waves provide an estimate of the rate at which signals progress from peripheral to more central levels of the auditory pathway. Given their anatomical origins, and parallels with the progression of development throughout the nervous system, latencies of the later components of the BAEP (i.e., Waves III and V) are the least mature in newborn infants. This reflects incomplete neural myelination of the fibers in the auditory pathway, reduced axon diameter, and immaturity in synaptic function (Eggermont & Salamy, 1988; Folsom & Wynne, 1987) that mature over the first 18 months of life.

The associations detected in the current study between fetal measures and conduction of Wave V and the III–V interval reflect activity focused in the later maturing regions of the brainstem auditory pathway. The relative degree of immaturity in these components in the newborn ensures greater detection of interindividual variation. The notion that BAEP provides a marker of functional integrity of the nervous system beyond the confines of the auditory pathway has been supported by studies that find reductions in auditory pathway conduction following prenatal exposures known to negatively impact postnatal development, such as lead (Rothenberg et al., 2000) and accelerated conductivity following postnatal exposures that enhance development, such as supplementation with docosahexaenoic acid (Unay et al., 2004). BAEP also corresponds to neurodevelopmental pathologies (Jiang et al., 2008). With respect to the current findings, it should be noted that the auditory brainstem pathway lies in close proximity to neural units that control heart rate and breathing (Amin, Charafeddine, & Guillet, 2005). More importantly, the predicted absence of any associations with fetal motor activity and the consistent associations with both FM–FHR coupling and FHR variability confirm speculation that the latter measures better reflect neural integrity of the developing fetus whereas fetal motor activity may more accurately provide an indication of temperament. However, this discussion needs to be qualified by the fact that less than half the original sample generated BAEP data so findings should be regarded as more preliminary than definitive. Home recording of evoked potentials with portable equipment is a particularly challenging undertaking as BAEPs consist of bioelectrical events in the microvolt range and are highly susceptible to interference from ambient and electrical noise in the home environment. Nonetheless, the fairly consistent findings provide support for conservation and/or prediction of neonatal neural maturation from fetal indicators.

The prenatal models generated from this study also serve to extend our prior work documenting normal ontogeny of fetal neurobehavioral development by providing continuously generated gestational data in weekly intervals. In general, these confirmed developmental trajectories that had previously been generated by data collected in monthly intervals. These include significant increases in FHR variability and FM–FHR coupling and little or no change in fetal motor activity (DiPietro et al., 2004). There was one exception; in prior studies, significant changes in slope were detected at 32 and 28 weeks gestation for FM–FHR coupling and FHR variability, respectively, such that the rate of development slowed near the end of gestation. The current study confirmed the developmental transition for FM–FHR coupling but not variability. This suggests that the longer interval between sampling in the prior report, which was 4 weeks, may have contributed to the perception of discontinuity in contrast to the more gradual change revealed by weekly measurement.

The third aim of the current study was to investigate the contributory role of maternal stress and anxiety on both the fetus and newborn. Stress is a broad construct to operationalize; in this study we focused on the types of stressors, both positive and negative, that are specific to pregnancy, as these have particular salience to the pregnant woman. For the sample as a whole, significant associations were detected with maternal stress but not anxiety. Fetuses of women with higher levels of maternal pregnancy-specific stress displayed higher levels of FHR variability and steeper incline in somatic–cardiac coupling as term approached. Variability in heart rate has been well documented as an indicator of parasympathetic maturation in both the prenatal (Martin, 1978) and postnatal (Bar-Haim, Marshall, & Fox, 2000; Porges, 1983) periods. Increases in synchronous activation of somatic and cardiac processes is a conspicuous feature of neurobehavioral development during gestation and has been similarly implicated as a marker for neural integration (Johnson et al., 1992) and fetal well-being (Baser et al., 1992). Thus, contemporaneous maternal stress appears to have facilitative effects on fetal neurodevelopment.

In addition, fetuses of women with higher stress were found to be marginally more active; replicating an earlier report using the same measure of maternal stress (DiPietro, Hilton, Hawkins, Costigan, & Pressman, 2002). Unlike the other two fetal measures, there is no compelling conceptual basis to regard variation in fetal motor activity along a continuum of maturation such that higher activity is either better or worse than lower activity. Instead, as in infants, fetal motor activity may best be considered as an indicator of temperament (Eaton & Saudino, 1992). Two studies have reported that maternal cortisol is positively correlated with fetal activity level (DiPietro, Kivlighan, Costigan, & Laudenslager, 2009; Field, Diego, Hernandez-Reif, Gil, & Vera, 2005), suggesting a potential mechanism for the effects observed here.

In the postnatal period, maternal prenatal stress was positively associated with neonatal irritability. This finding partially supports others that detect associations between higher maternal prenatal stress or anxiety and less infant behavioral regulation and/or greater reactivity to novelty measured by observational methods (Davis et al., 2004; Gutteling et al., 2005; Huizink et al., 2002) although another study reports the reverse association (Mohler, Parzer, Brunner, Wiebel, & Resch, 2006). However, in the current study, prenatal stress was also associated with faster neural conduction for three of the four BAEP latencies. In a prior report on a different sample, we found that maternal prenatal stress was associated with higher Bayley Scales of Infant Development scores at age 2, after controlling for postnatal maternal psychological measures (DiPietro et al., 2006). However, there is significant concern regarding the degree to which indicators of mental and motor development as measured by standard developmental assessments adequately reflect information processing, which is at the core of early brain development. Thus, BAEP results in the present study provide perhaps more compelling support for the maturative role of maternal prenatal stress on development as BAEP was measured closer to birth and is unambiguously representative of neural processing of information. Together, the postnatal findings suggest that dimensions of information processing and temperament should be regarded as fairly distinct systems, and efforts to measure the former should be careful to exclude confounding influences of the latter.

The current literature detailing maternal stress effects on human development is long on theories of why maternal stress is damaging to the fetus but short on empirical data. Most conceptualization is based on animal models, which use an experimental approach to delivering repetitive, stressful events. These are quite different from human models, which necessarily rely on an observational approach to maternal appraisal of elements within their lives, which in turn is confounded by dispositional features of maternal temperament (DiPietro, 2004). Although evidence from animal models often supports deleterious consequences in experimental paradigms (e.g., Weinstock, 2001), functional deficits are not uniformly found. For example, rodents subjected to mild stress showed better spatial learning coupled with facilitated differentiation in neuronal morphology (Fujioka et al., 2001) and more exploratory behavior (Meek, Burda, & Paster, 2000). Moreover, methodologies routinely used in human studies have significant limitations. Some of the most widely cited studies in support of an adverse role of maternal stress on behavioral or cognitive development include the following design problems: reliance on maternal report of child outcomes, as opposed to observational data collection, thereby inextricably confounding the dependent and independent (i.e., maternal psychological distress) measures in a direction that promotes detection of positive associations; failure to adequately control for postnatal maternal psychological distress, which confers well-known, independent effects on child development as a result of environmental, as opposed to biological, mediation; and lack of control for disparities in social class within samples when it is linked to both exposure and outcomes.

Although the findings reported herein may be counterintuitive to some readers, they are consistent with the orientation that the human brain requires sufficient, but not excessive, stress to promote neural development both before (Amiel-Tison et al., 2004) and after (Huether, 1998) birth. It is important to note that the sample in this study is composed of well-educated, financially stable women with well-nourished pregnancies, and as such, the findings may not generalize to populations of women with psychopathology or to those that experience the types of chronic stressors associated with poverty. In terms of a recently proposed lexicon for the consequences of stress exposure on child development, fetal exposures to stress in this sample would likely fall into the categories of "positive" (i.e., moderate, short-lived exposures) or "tolerable" (i.e., time limited and within a supportive environment) as opposed to "toxic" levels that exceed the capabilities of full recovery (Shonkoff, 2006).

No sex differences in development during the fetal period were evident, confirming findings reported on other samples of similar size (DiPietro et al., 2004; Robles de Medina, Visser, Huizink, Buitelaar, & Mulder, 2003). In the postnatal period, however, boys had significantly slower BAEP conduction in three of the four latency measures, suggesting slower neural maturation. Given the equivalence in anthropometric indicators of growth between boys and girls, these findings cannot be attributed to conductance differences secondary to size. Instead, they support the long-standing recognition that girls are more mature than boys at birth (Tanner, 1978). In addition, there was differential effect of pregnancy-specific stress exposure on both types of newborn outcomes such that the positive associations between stress and neonatal irritability and neural conduction scores were greater for boys than girls. A pattern of differential responsiveness in neonatal maturity to maternal stress hormones between boys and girls has recently been shown (Ellman et al., 2008). These results suggest that features of the intrauterine environment may interact with fetal sex in ways that remain largely unknown and unexplored.

In summary, the current results provide normative data regarding predictors of neonatal maturation in a sample of healthy women with normally progressing pregnancies. This information provides a basis for future examination of the manner in which early experiences associated with adversity in the maternal environment, intrauterine stress, or exposure to potentially deleterious substances may exert influence on the fetus, and in turn, the child.

The Timing of Prenatal Exposure to Maternal Cortisol and Psychosocial Stress Is Associated With Human Infant Cognitive Development

Elysia P. Davis and Curt A. Sandman
University of California, Irvine

The consequences of prenatal maternal stress for development were examined in 125 full-term infants at 3, 6, and 12 months of age. Maternal cortisol and psychological state were evaluated 5 times during pregnancy. Exposure to elevated concentrations of cortisol early in gestation was associated with a slower rate of development over the 1st year and lower mental development scores at 12 months. Elevated levels of maternal cortisol late in gestation, however, were associated with accelerated cognitive development and higher scores at 12 months. Elevated levels of maternal pregnancy-specific anxiety early in pregnancy were independently associated with lower 12-month mental development scores. These data suggest that maternal cortisol and pregnancy-specific anxiety have programming influences on the developing fetus.

The prenatal period is a time of rapid change during which fetal organs and organ systems are forming and are vulnerable to both organizing and disorganizing influences. These influences on the fetus have been described as programming; the process by which a stimulus or insult during a vulnerable developmental period has a long-lasting or permanent effect. The effects of programming are dependent on the timing of the exposure and on the developmental stage of organ systems. There is convincing support for fetal programming of adult health outcomes; however, the evidence comes primarily from retrospective studies that rely on birth phenotype (e.g., small size at birth or preterm delivery) as an index of fetal development (Barker, 1998, 2002). It is unlikely, however, that birth phenotype alone is the cause of subsequent health outcomes. Birth phenotype, instead, reflects fetal adaptation to exposures that shape the structure and function of physiological systems that underlie health and disease risk (Gluckman & Hanson, 2004; Morley, Blair, Dwyer, & Owens, 2002). One emerging risk factor for health outcomes resulting from fetal programming is prenatal exposure to maternal stress signals. The purpose of the present study was to investigate the programming influence of biological and psychosocial indicators of prenatal maternal stress for fetal development and to evaluate the effects of timing of exposure to stress on infant development.

Fetal Programming: The Role of Glucocorticoids (GCs)

For a number of reasons, GCs have been proposed as a primary candidate for fetal programming. GCs cortisol in humans, are steroid hormones that play a critical role in normal development and are the end product of the hypothalamic–pituitary–adrenal (HPA) axis, one of the body's major stress responsive systems. HPA axis activity is regulated by the release of hypothalamic corticotrophin-releasing hormone (CRH), which stimulates the biosynthesis and release of adrenocorticotropic hormone (ACTH). Release of ACTH from the pituitary into the blood stream triggers cortisol production and release from the adrenal cortex. Cortisol is released into the general circulation and has effects on nearly every organ and tissue in the body (Munck, Guyre, & Holbrook, 1984). In human pregnancy, regulation of the HPA axis changes dramatically with the production and release of CRH from the placenta. In contrast to the role of cortisol in the negative feedback regulation of the HPA axis, cortisol stimulates placental CRH production resulting in a positive feedback loop that allows for the simultaneous increase of CRH,

ACTH, and cortisol in the maternal and fetal compartments over the course of gestation (King, Nicholson, & Smith, 2001; Petraglia, Florio, Nappi, & Genazzani, 1996).

Maternal cortisol increases two- to fourfold over the course of normal gestation (Mastorakos & Ilias, 2003; Sandman et al., 2006). Fetal exposure to the increasing concentrations of maternal cortisol is regulated by a placental enzyme, 11β-hydroxysteroid dehydrogenase type 2 (11β-HSD2), which oxidizes cortisol to its inactive form cortisone (Beitens, Bayard, Ances, Kowarski, & Migeon, 1973; Brown et al., 1996). Activity of placental 11β-HSD2 also increases as pregnancy advances, providing partial protection for the fetus from maternal cortisol during critical stages of development. Toward the end of pregnancy, however, activity of the placental enzyme decreases, allowing a larger proportion of maternal cortisol to reach the fetus (Giannopoulos, Jackson, & Tulchinsky, 1982; Murphy, Smith, Giles, & Clifton, 2006). The normal increase in maternal cortisol during gestation and the decrease in placental 11β-HSD2 activity at the end of pregnancy ensure that the fetus is exposed to sufficient levels of cortisol during the third trimester, which are important for maturation of the fetal lungs and for preparation of the fetus for delivery (Austin & Leader, 2000; Hacking, Watkins, Fraser, Wolfe, & Nolan, 2001). Because placental 11β-HSD2 is only a partial barrier, active maternal cortisol passes through the placenta, and fetal cortisol levels are significantly correlated with maternal levels throughout gestation (Gitau, Cameron, Fisk, & Glover, 1998; Gitau, Fisk, Teixerira, Cameron, & Glover, 2001). GC receptors are present throughout the central nervous system (Diorio, Viau, & Meaney, 1993; Jacobson & Sapolsky, 1991; Sanchez, Young, Plotsky, & Insel, 2000) and GCs easily pass through the blood–brain barrier (Zarrow, Philpott, & Denenberg, 1970). GCs play a critical role in normal brain development, which provides further evidence for GCs as a mechanism for programming the fetus (Matthews, 2000; Trejo, Cuchillo, Machin, & Rua, 2000; Welberg & Seckl, 2001).

GCs shape the development of the neural systems involved in the regulation of emotion and cognitive function. Furthermore, moderate increases in GCs have salutary effects on both brain development and behavioral regulation (Kapoor, Dunn, Kostaki, Andrews, & Matthews, 2006). For example, rodents exposed in the early postnatal period to moderate increases in GCs display decreased physiological and behavioral stress responses, persisting improvements on cognitive tasks assessing learning and memory, and increased neural plasticity (Catalani et al., 2002; Scaccianoce, Catalani, Lombardo, Consoli, & Angelucci, 2001; Trejo et al., 2000). Exposure to excess GCs, however, particularly during vulnerable periods, appears to be neurotoxic (Uno et al., 1990; Uno et al., 1994). Animal models have demonstrated that prenatal exposure to administration of high levels of synthetic GCs has profound and lasting consequences for offspring including increased stress reactivity (Coe & Lubach, 2005; Hauser et al., 2007), poorer performance on cognitive tasks (Brabham et al., 2000), and impaired brain development, particularly in terms of reduced hippocampal volume (Bruschettini, van den Hove, Gazzolo, Steinbusch, & Blanco, 2006; Coe & Lubach, 2005; Uno et al., 1994). The few studies that have assessed the effects of prenatal treatment with a high dose of synthetic GCs in humans (given to women at risk of preterm delivery for maturation of fetal lungs) have documented consequences for emotional disturbances in early childhood (French, Hagan, Evans, Godfrey, & Newnham, 1999), dysregulated stress responses in infancy (Davis, Townsend, et al., 2004; Davis et al., 2006), impaired memory in school-aged children (MacArthur, Howie, Dezoete, & Elkins, 1982) and neurodevelopmental delays in toddlers (Spinillo et al., 2004; Wapner et al., 2007).

There are only a handful of studies that have evaluated the role that endogenous maternal cortisol plays in shaping human fetal development. Prenatal exposure to elevated maternal cortisol has been shown to predict increased fussiness, negative behavior and fearfulness in infancy (Davis et al., 2007; de Weerth, van Hees, & Buitelaar, 2003), and greater cortisol reactivity in childhood (Gutteling, de Weerth & Buitelaar, 2005). Only one group has evaluated the effects of endogenous maternal cortisol during pregnancy on infant cognitive and motor development. Huizink, Robles de Medina, Mulder, Visser, and Buitelaar (2003) have shown that elevated prenatal maternal cortisol during the third trimester was associated with delays in mental development at 3 months and motor development at 3 and 8 months. A limitation of these studies with humans is that it is difficult to separate shared genetic effects on emotion and stress regulation from direct effects of maternal cortisol. However, in conjunction with animal models where random assignment is possible and human studies involving synthetic GC administration, these studies suggest that prenatal exposure to endogenous maternal cortisol has a programming influence on the developing nervous system.

Fetal Programming: The Role of Maternal Psychosocial Stress

During pregnancy, maternal psychosocial stress threatens the fetal nervous system and shortens the length of gestation. In humans, the most well-documented effects of exposure to maternal stress is on birth outcomes including preterm delivery (Copper et al., 1996; Dole et al., 2003; Glynn, Dunkel Schetter, Hobel, & Sandman, 2008; Glynn, Wadhwa, Dunkel Schetter, & Sandman, 2001; Hobel & Culhane, 2003). Less is known about the consequences of prenatal maternal stress for human development independent of birth outcome. Numerous studies with rodent models have shown pervasive detrimental effects of exposure to prenatal maternal stress for the offspring (Dickerson, Lally, Gunnel, Birkle, & Salm, 2005; Kapoor, Petropoulos, & Matthews, 2008; Maccari & Morley-Fletcher, 2007; Van den Hove et al., 2005). Similarly, exposure of nonhuman pregnant primates to behavioral stressors during the prenatal period is associated with enhanced stress reactivity (Clarke, Wittwer, Abbott, & Schneider, 1994), compromised neuromotor development (Schneider & Coe, 1993; Schneider, Coe, & Lubach, 1992), irritable temperament (Schneider, 1992), poor attention regulation (Schneider, Roughton, Koehler, & Lubach, 1999), and impaired brain development, specifically reduced neurogenesis in the dentate gyrus (Coe et al., 2003). Stress early in gestation had more serious consequences for offspring than later gestational stress (Mueller & Bale, 2007; Schneider et al., 1999), although not all studies have found an effect of timing of exposure (Coe et al., 2003). The ability to generalize to humans from animal models is limited by the vast differences in reproductive physiology, even in closely related species, such as humans and nonhuman primates (Power et al., 2006) and by the significant differences in the type of prenatal stress employed with different species (e.g., physical restraint in rodents vs. report of stress in humans).

A small but growing literature with human populations has established that prenatal exposure to elevated levels of maternal stress is associated with behavioral and emotional disturbances during infancy and childhood, after controlling for postpartum maternal psychological distress, including postpartum depression (Bergman, Sarkar, O'Connor, Modi, & Glover, 2007; Davis et al., 2007; Davis, Snidman, et al., 2004; Gutteling, de Weerth, & Buitelaar, 2005; Huizink, De Medina, Mulder, Visser, & Buitelaar, 2002; O'Connor, Heron, & Glover, 2002). Effects of prenatal maternal stress on cognitive and motor development are less clear. There is evidence that maternal self-report of elevated stress and anxiety during the prenatal period is associated with delayed infant cognitive and neuromotor development (Brouwers, van Baar, & Pop, 2001; Huizink et al., 2003) and that these deficits may persist into adolescence (Mennes, Stiers, Lagae, & Van den Bergh, 2006). However, not all studies have demonstrated such an association (Brouwers et al., 2001; DiPietro, Novak, Costigan, Atela, & Ruesing, 2006; Van den Bergh, 1990) and is possible that generalized self-report measures of psychological distress do not adequately characterize stress that is unique during pregnancy. Evidence is emerging that measures of pregnancy-specific stress are better than measures of generalized psychological distress for predicting developmental outcomes including preterm delivery (DiPietro, Ghera, Costigan, & Hawkins, 2004; Roesch, Dunkel-Schetter, Woo, & Hobel, 2004), fetal behavior (DiPietro, Hilton, Hawkins, Costigan, & Pressman, 2002), infant cognitive and motor development (DiPietro et al., 2006; Huizink et al., 2003), infant emotional regulation (DiPietro et al., 2006), and child brain development (Buss, Davis, Muftuler, Head, & Sandman, in press).

Summary

During the prenatal period, maternal signals of stress have a programming influence on the developing fetus and it is possible that these signals have different consequences as gestation advances. There are, however, few prospective studies with humans that have addressed this question. Given the vast changes in both maternal physiology and fetal development during the prenatal period, characterization of the effects of prenatal maternal cortisol and psychosocial stress for development requires multiple longitudinal assessments during gestation. The goals of the current study were to determine, first, whether maternal cortisol and maternal and psychological stress during pregnancy were associated with cognitive and motor development in the offspring independent of postpartum influences, and second, whether there was a sensitive period for these effects on development.

Method

Participants

Study participants included mother–infant pairs from an ongoing longitudinal study of prenatal stress and development. Women with singleton pregnancies less than 16 weeks gestational age (GA) were recruited from obstetric clinics in Southern California and followed longitudinally from early pregnancy to 12 months postpartum. Women who were English speaking, nonsmokers, over the age of 18, did not take steroid medication, and for whom there was no evidence for drug or alcohol use during pregnancy were eligible for participation in this study. The current sample included the first 125 full-term infants (60 girls and 65 boys) and their mothers to complete the 12-month assessment. Women gave informed consent for all aspects of the protocol, which was approved by the Institutional Review Board for Protection of Human Subjects. Descriptive information for the study sample is shown in Table 1. All infants were full term at birth (*M* GA = 39.2 weeks, *SD* = 1.1 weeks; *M* weight = 3436 g, *SD* = 447 g). Infants in this sample were stable at the time of delivery and had a median 5-min Apgar score of 9 (range = 8–10).

Procedures

Maternal saliva samples were collected for cortisol analyses and maternal psychological state (state anxiety, perceived stress, and pregnancy-specific anxiety) was assessed at five intervals during pregnancy (Time 1: 15.1 ± 0.89; Time 2: 19.1 ± 0.93; Time 3: 25.4 ± .95; Time 4: 30.8 ± 0.69; Time 5: 36.6 ± 0.61 weeks of gestation). Maternal depression was assessed at the first four visits. Infant mental and psychomotor development was evaluated at 3 (*M* = 3.1, *SD* = 0.27), 6 (*M* = 6.2, *SD* = 0.3), and 12 (*M* = 11.9, *SD* = 0.3) months of age. At the three postnatal assessments, maternal state anxiety, perceived stress, depression, and parenting-specific stress were measured. The postpartum assessments of maternal psychological state were included to control for the potential influence of maternal affect during the postnatal period on infant development. Additionally, prenatal medical history and obstetric risk were obtained from extensive medical interviews conducted by a research nurse and through review of prenatal and hospital medical records.

Table 1
Demographic Information for the Study Sample

	Study sample (*N* = 125)
Maternal age at delivery	29.9[a]
Married (%)	79
Primiparous (%)	48
Education (%)	
High school or equivalent	95
College graduate	46
Annual household income (%)	
$0–$30,000	17
$30,001 to $60,000	26
$60,001 to $100,000	33
Over $100,000	24
Race/ethnicity (%)	
Non-Hispanic White	50
Hispanic	30
Asian	10

[a] *SD* = 5.3, range = 19–41.

Measures

Salivary cortisol assessment. Saliva samples were collected in the early afternoon, at least 1 hr after the participant had eaten (mean time of day ranged from 13:19 to 13:30 across the five assessment intervals) using a Salivette sampling device (Sarstedt, Numbrecht, Germany). Within this restricted range of sample collection time, time of day was not associated with cortisol levels (all *r*s < .15, all *p*s > .10).

Saliva samples were spun and stored at −70°C until assayed. Thawed samples were centrifuged at 1500 × g for 15 min before assay. Salivary cortisol levels were determined by a competitive luminescence immunoassay (LIA; IBL-America, Minneapolis, MN) with reported detection limits of 0.015 μg/dl. The cross reactivity of the assay was < 2.5% with cortisone, prednisone, and corticosterone and < 0.1% with other naturally occurring steroids. The intra- and interassay coefficients of variance are 5.5% and 7.6%, respectively. Data reduction for the LIA assay was done by an automated four-parameter logistics computer program (software Mikro Win 2000; Berthold Microplate Luminometer, Berthold Detection Systems GmbH; Pforzheim, Germany). One maternal sample from the second prenatal visit was removed because it was more than 4 *SD* above the mean. All samples were assayed in duplicate and averaged. A square root transformation was implemented to reduce skewedness. All values reported in the text, tables and graphs are raw μg/dl levels to facilitate interpretation.

Maternal psychological assessments. Generalized or nonspecific stress was evaluated using the 12-item version of Cohen's Perceived Stress Scale (PSS; Cohen, Kamarck, & Mermelstein, 1983). The PSS evaluated participants' feelings about how they were able to handle day-to-day problems and hassles, how often they felt nervous and stressed, and how often they felt things were going well. Responses were made on a 5-point Likert scale ranging from 1 (*never*) to 5 (*almost always*) and the final score could range from 12 to 60. This measure has been used extensively with nonpregnant and pregnant samples (Culhane et al., 2001; Glynn et al., 2008) and been shown to have both good internal consistency ($\alpha = .80$) and validity (Cohen et al., 1983).

The short form of the Center for Epidemiological Studies Depression Inventory was used to evaluate maternal depression (CES–D; Santor & Coyne, 1997). Responses to each of the nine items in this measure were recorded on a 4-point Likert scale with a range of 0–3. Anchor points, in terms of days per week, were *rarely or none of the time (less than 1 day)* to *most or all of the time (5–7 days)*. The final score could range from 0 to 27, with a higher score indicating greater impairment. This measure has been extensively used and published studies demonstrate both internal consistency ($\alpha = .84$) and validity of this measure (Santor & Coyne, 1997). The CES–D is a frequently used instrument for the study of depression in the general population and has been validated in pregnant samples (Marcus, Flynn, Blow, & Barry, 2003). Scores on the CES–D during pregnancy are associated with birth outcome and infant development (Davis et al., 2007; Lundy et al., 1999).

The 10-item State Anxiety subscale of the State-Trait Personality Inventory (STAI; Speilberger, 1983) was used to measure state anxiety. The STAI assessed the degree to which participants had experienced anxiety-related symptoms or emotions. Responses were made using a 4-point Likert scale ranging from 1 (*not at all*) to 4 (*very much*) and scores could range from a minimum of 10 to a maximum of 40. The STAI has been used for research purposes with both pregnant (Glynn et al., 2008; Rini, Dunkel-Schetter, Wadhwa, & Sandman, 1999) and nonpregnant samples. The STAI has good internal consistency with a Cronbach's alpha coefficient of .92 (Spielberger, 1983).

The 10-item Pregnancy Specific Anxiety (PSA) scale was used to measure a woman's feelings about her health during pregnancy, the health of her baby, and her feelings about labor and delivery. Answers were given on a 4-point Likert scale ranging from 1 (*not at all*) to 4 (*very much*) and included items such as: "I am fearful regarding the health of my baby," "I am concerned or worried about losing my baby," and "I am concerned or worried about developing medical problems during my pregnancy." The final score on this measure could range from 10 to 40. This reliable measure was specifically developed for use in pregnancy research and has good internal consistency (αs = .75–.85; Glynn et al., 2008; Rini et al., 1999).

The 36-item Parenting Stress Index (PSI) is a measure designed to identify stress within the parent–child relationship. Responses were given on a 5-point Likert scale. This measure includes items such as: "I find myself giving up more of my life to meet my children's needs than I ever expected" and "My child rarely does things for me that make me feel good." The total score could range from 36 to 180. The PSI has good internal consistency ($\alpha = .95$; Albidin, 1995).

Medical Risk and Obstetric History

An extensive structured medical interview was conducted by a research nurse at the participants' first prenatal visit to assess pregnancy history and to identify risk factors that might affect pregnancy outcome. At each subsequent visit, a follow-up interview was conducted to characterize pregnancy-related changes in maternal health. Maternal and infant medical records were reviewed to assess prenatal medical history and birth outcome. A binary score assessing the presence or absence of prenatal medical risk was derived (Hobel, 1982). The risk factors considered were infection, hypertension, diabetes, oligohydramnios, polyhydramnios, preterm labor, vaginal bleeding, placenta previa and anemia, in the index pregnancy. Additionally, birth order, GA at birth, birth weight, and Apgar scores were recorded.

Infant Development

Infant development was assessed using the Bayley Scales of Infant Development, 2nd ed. (BSID–II). Examiners were trained by a clinician with over 15 years of experience with the BSID and were directly supervised by a clinical psychologist. Videotaped assessments were reviewed monthly. Interrater reliability, calculated on 20% of the assessments at each age, was 95% at 3 and 6 months and 93% at 12 months. The BSID is a standardized developmental assessment (Bayley, 1993). Measures of development were obtained at each age using the Mental Developmental Index

(MDI) and Psychomotor Development Index (PDI). Sample items from the MDI and PDI at each age are presented in Table 2. Reliability coefficients on the BSID were .83, .92, and .88 for MDI and .84, .84, and .84 for PDI at 3, 6, and 12 months of age, respectively. Conventional scoring of the BSID created composite MDI and PDI scaled scores by summing the total number of items achieved, corrected for basal effects. The raw scores were converted to scaled scores by reference to a developmental table. Mean score raw scores and scaled scores for the MDI and PDI are presented in Table 3.

Data Analysis

Preliminary analyses were performed using regressions and *t* tests to identify sociodemographic (i.e., race/ethnicity, marital status, education, and household income), pregnancy-related (i.e., prenatal medical risk), and infant (i.e., GA at birth, sex, birth order, and ever breastfed) variables that might influence infant cognitive or motor development. The factors associated with infant outcomes with a p value of .10 or less were GA at birth (MDI and PDI; $p < .01$), maternal race ($p < .10$), prenatal medical risk (MDI only; $p = .10$), and birth order (PDI only; $p < .01$). None of the assessments of postnatal maternal psychological state (state anxiety, depression, or perceived stress) significantly predicted infant development (all $ps > .2$). Furthermore, maternal report of stress within the parent–child relationship was not significantly associated with infant development (all $ps > .2$). All variables that were associated with MDI or PDI in preliminary analyses (infant GA at birth, maternal race, birth order, and prenatal medical risk) were modeled as covariates. Although postnatal measures of psychological distress were not significantly associated with infant MDI or PDI at 3, 6, or 12 months, models were tested with and without these measures. Adjusting for postnatal maternal psychological distress did not change the statistical significance of the results in any of the analyses described below.

Hierarchical linear modeling (HLM) growth curve analyses (Raudenbush & Bryk, 2002; Singer & Willett, 2003) were used to describe both the trajectory of the prenatal indicators of maternal stress (maternal cortisol and psychosocial measures) across pregnancy and the trajectory of infant development as assessed with the BSID. HLM models were used to determine whether the patterns of prenatal endocrine and psychosocial stress measures were associated with individual differences in infant development. HLM, when used with repeated measures, treats the data in a hierarchical fashion with observations nested within persons. This approach allows variance to be modeled at multiple levels and provides several advantages over ordinary least squares regression (Raudenbush & Bryk, 2002). First, standard regression or analysis of variance (ANOVA) models are limited to one component of variability, the deviation of the individual from the group mean. In contrast, HLM includes the within-person variability assessed over time. Second, estimates of goodness of fit in modeling each individual's data are derived, and the most reliable data are given greater statistical weight. Third, HLM produces robust estimates despite missing values for the repeated dependent measure. Ninety-nine participants had complete data at all prenatal assessments. Twenty-three participants were missing data

Table 2
Sample Items From the Mental and Psychomotor Scales

	Mental Scale	Psychomotor Scale
3 months	Discriminates novel visual pattern	Elevates self by arms
	Eyes follow rod	Sits with support
	Reaches for suspended ring	Balances head
6 months	Lifts inverted cup	Uses whole hand to grasp pellet
	Looks for fallen spoon	Sits alone
	Pulls string to secure ring	Turns from back to stomach
12 months	Puts one cube in cup	Walks alone
	Responds to spoken request	Throws ball
	Places one puzzle piece	Squats briefly

Table 3
Descriptive Information (Mean and Standard Deviation) for Infant BSID Scores

	Infant age		
	3	6	12
Mental development raw score	30.4 (3.3)	61.2 (4.3)	84.9 (4.3)
MDI scaled score	92.8 (5.9)	96.6 (8.8)	93.1 (10.3)
Psychomotor development raw score	23.1 (2.8)	40.0 (4.2)	64.1 (4.3)
PDI scaled score	93.7 (8.6)	97.3 (12.9)	97.1 (16.8)

Note. BSID = Bayley Scales of Infant Development, 2nd ed. (BSID–II); MDI = Mental Developmental Index; PDI = Psychomotor Development Index.

from one visit and 3 participants were missing data from two visits. One hundred twelve participants had complete data at all postnatal assessments. Eight participants were missing data from one visit and 5 participants were missing data from two visits. In HLM models cases with complete data are weighted more heavily, but all cases are included in the estimation of effects. Finally, HLM uses precise measures of timing (i.e., gestational week) of data collection rather than nominal estimates of assessment intervals.

Using HLM, two sets of analyses were performed. The first analysis was implemented to examine whether prenatal maternal stress measures at a given prenatal assessment predicted the trajectory of infant development over the first postnatal year. In these analyses, both mental and motor performance at a given age (3, 6, and 12 months) and developmental trajectories (slope) over the first postnatal year were assessed. To characterize developmental trajectories, raw data (rather than scaled scores) from the mental and psychomotor scales were used in these analyses. Data were modeled at the exact age in weeks that infants were tested to account for variability in assessment age. The second set of analyses assessed the profile or trajectory of prenatal maternal stress measures that was associated with infant performance at 12 months using scaled scores determined based on developmental norms for the BSID.

Predicting Trajectories of Infant Development

To determine whether prenatal maternal stress measures predicted the trajectory of infant development across the first postnatal year, two-level models were constructed. For these analyses, raw data from the mental and psychomotor scales were used so that the trajectory of development could be assessed. Level 1 variables, or those evaluated longitudinally across the first postnatal year, included: infant mental and psychomotor development (raw data) and infant age in weeks entered as continuous variables. In all cases, a linear model best fit the data. Maternal stress measures (cortisol, perceived stress, state anxiety, pregnancy-specific anxiety, and depression) measured at each of the five prenatal assessments and entered as continuous variables were modeled at Level 2. Prenatal predictors were assessed at each of the five prenatal assessment time points. Time-invariant variables that satisfied criterion for inclusion as covariates (GA at birth, race/ethnicity [Hispanic: 0 = no, 1 = yes; White: 0 = no, 1 = yes], prenatal medical risk [MDI only; 0 = no, 1 = yes], and birth order [PDI only; 0 = firstborn, 1 = later born]) were included at Level 2. For each Level 1 variable, the models were tested for differences in slope and intercept at 3, 6, and 12 months of age.

Patterns of Maternal Biosocial Stress Associated With Infant Outcomes

At the infant ages where significant associations were found between predictor and outcome variables, a second set of analyses was performed to characterize the profile of maternal stress across pregnancy that was associated with infant outcomes at a given age. In all cases, predictor and outcome variables were modeled as continuous variables. For these analyses, two-level models were constructed to evaluate maternal cortisol and psychosocial stress trajectories across pregnancy. Level 1 variables, or those evaluated longitudinally across the five prenatal assessment days, included: maternal cortisol, psychosocial measures (perceived stress, state anxiety, pregnancy-specific anxiety, and depression), and gestational week. A linear model was applied in all cases except for pregnancy-specific anxiety, where a quadratic function was a better fit, $\chi^2(3) = 12.1, p < .01$.

BSID scores (MDI and PDI), entered as continuous variables, were the outcomes of interest and were modeled at Level 2. Time-invariant variables that satisfied criterion for inclusion as covariates (GA at birth, race/ethnicity [Hispanic: 0 = no, 1 = yes; White: 0 = no, 1 = yes], prenatal medical risk [MDI only; 0 = no, 1 = yes], and birth order [PDI only; 0 = firstborn, 1 = later born]) as well as postnatal measures of psychosocial distress were included at Level 2. For each Level 1 variable, the model was tested for differences in slope and intercept at all time points within the range of actual endocrine and psychosocial assessments (13–38 weeks of gestation). Individual slope and intercept values were retained from significant models. The values that were most strongly associated with infant outcomes were entered into stepwise and hierarchical regression models to determine whether maternal psychosocial and endocrine stress measures jointly or independently predicted BSID scores.

Results

Infant Development

The unconditional growth model was significant indicating that mental ($t = 105.2$, $p < .001$) and psychomotor ($t = 108.3$, $p < .001$) performance (raw scores) improved across the first postnatal year (see Table 3). As expected, scaled scores calculated with reference to developmental norms, did not increase ($p > .30$). Table 4 shows the correlation between mental and psychomotor development scaled scores across the three assessment time points. As illustrated, modest stability is seen in BSID scores with a stronger association among temporally adjacent measures.

Maternal Cortisol

The unconditional growth model was significant, indicating that, as expected, salivary cortisol levels increased across gestation ($t = 13.6$, $p < .001$). Salivary cortisol levels increased from .27 at 15 gestational weeks to .61 at 37 gestational weeks. Table 5 shows the correlation between cortisol measures across pregnancy. Moderate correlations were seen between temporally adjacent assessments.

Maternal Psychological State

Maternal perceived stress ($Ms = 20.1$ to 21.6), depression ($Ms = 13.7$ to 15.1), and state anxiety ($Ms = 17.7$ to 18.6) did not significantly change over the course of pregnancy ($ps = .06$ to .30). Pregnancy-specific anxiety changed significantly across gestation ($t = 3.4$, $p < .01$). Levels were highest early in pregnancy and decreased through mid-gestation. Mean PSA scores ranged from 17.3 to 18.7.

Each of the four psychosocial measures was stable over pregnancy. Within each measure intercorrelations ranged from .51 to .75 during pregnancy. Not only were scores on the psychosocial measures stable during the prenatal period, but as expected, concurrent measures of state anxiety, perceived stress, and depression were intercorrelated (average $rs = .66$, $ps < .001$). The associations between these measures and PSA were lower but also significant (average $rs = .41$, $ps < .001$).

During the postnatal period, levels of state anxiety ($Ms = 16.8$ to 17.5), perceived stress ($Ms = 20.1$ to 21.1), and depression ($Ms = 12.8$ to 12.9) were relatively stable ($rs = .45$ to .68) and concurrent measures were intercorrelated (average $rs = .67$). Mean levels of parenting stress ranged from 64.2 to 66.6 and parenting stress was relatively stable over the first postnatal year ($rs = .48$ to .67).

Prenatal Maternal Cortisol and Maternal Psychological State

Data indicate that maternal cortisol was not significantly associated with maternal anxiety, depression, or pregnancy-specific anxiety at any of the five prenatal assessment time points (all $rs < .18$). Prenatal maternal perceived stress was not associated with maternal cortisol at any of the prenatal assessment time points (all $rs < .13$) with the exception of the 36+ weeks' GA assessment. At this time point, maternal cortisol was negatively associated with perceived stress levels, $r(119) = -.21$, $p < .05$.

Maternal Prenatal Stress Measures and Trajectories of Infant Development

We first examined whether the rate of infant development over the first postnatal year was associated with prenatal cortisol at each assessment interval: 15, 19, 25, 31, and 37 weeks. For these analyses, raw scores (rather than scaled scores) were used so that developmental changes could be evaluated. Data indicate that the level of maternal cortisol both early and late in gestation predicted infant mental development. Lower maternal cortisol at the first prenatal assessment (15 weeks) predicted accelerated infant mental

$^*p < .05$. $^{**}p < .01$.

development (steeper slope of raw scores) across the first postnatal year ($t = -2.5$, $p < .01$), resulting in enhanced cognitive functioning at 12 months of age ($t = 2.4$, $p < .05$). Furthermore, higher maternal cortisol late in gestation (37 weeks) additionally predicted accelerated infant development (a steeper slope of raw MDI scores) over the first postnatal year ($t = 1.9$, $p < .05$), resulting in a tendency for higher mental development raw scores at 12 months ($t = 1.6$, $p = .10$). Maternal prenatal cortisol at 19, 25, and 31 week assessments did not predict the trajectory of infant development assessed using mental development raw scores. No measure of maternal cortisol at any time period predicted psychomotor development raw scores. None of the measures of maternal psychological distress (perceived stress, state anxiety, pregnancy-specific anxiety, and depression) were significantly associated with infant development using raw mental or psychomotor scores. These data suggest that the pattern of maternal cortisol during gestation predicts the trajectory of infant mental development over the first postnatal year resulting in significant differences in performance only at 12 months.

Patterns of Maternal Cortisol Associated With Infant Development

A second set of analyses were performed to identify the pattern of maternal cortisol that predicted optimal performance at 12 months. For these analyses, the scaled scores were used to allow for comparison to developmental norms. These models offer the additional advantage of assessing the slope or trajectory of maternal cortisol across gestation. As in the previous analyses, cortisol and BSID scores were modeled as continuous variables. As shown in Figure 1, infants scoring higher on the 12-month MDI were exposed to (a) lower maternal cortisol before 18 weeks GA (ts = −2.1 to −2.7, ps < .05), (b) an accelerated increase in maternal cortisol across gestation ($t = 3.7$, $p < .001$), and (c) higher maternal cortisol after 30 weeks GA (ts = 2.0 to 2.9, ps < .05). Interestingly, this profile of maternal cortisol additionally predicted whether or not 12-month-old infants received a score that would be categorized as delayed using standardized cutoff on the BSID (ps < .05). Because the intercepts that were the strongest predictors of a low MDI score were high maternal cortisol at 13 weeks GA and low maternal cortisol at 38 weeks GA, a stepwise regression model was implemented to determine whether early and late cortisol jointly or independently predicted MDI. The stepwise model indicated that, after entering covariates into the model, early and late cortisol independently predicted infant MDI (13-week GA intercept: $\Delta R^2 = .05$, $\beta = -.23$, $t = -2.5$, $p < .01$; 38-week GA intercept: $\Delta R^2 = .03$, $\beta = .17$, $t = 2.0$, $p < .05$). Together, early and late maternal cortisol accounted for 8% of the variance in infant cognitive performance, as assessed with the MDI. At 13 weeks of gestation, a 0.1 μg/dl increase in cortisol was associated with a 4-point decrease in MDI. At 38 weeks of gestation, a 0.1 μg/dl increase in cortisol was associated with a 2-point increase in MDI. PDI was not significantly associated with maternal cortisol levels (ps > .3).

To determine whether there was a profile of prenatal maternal cortisol that predicted infant

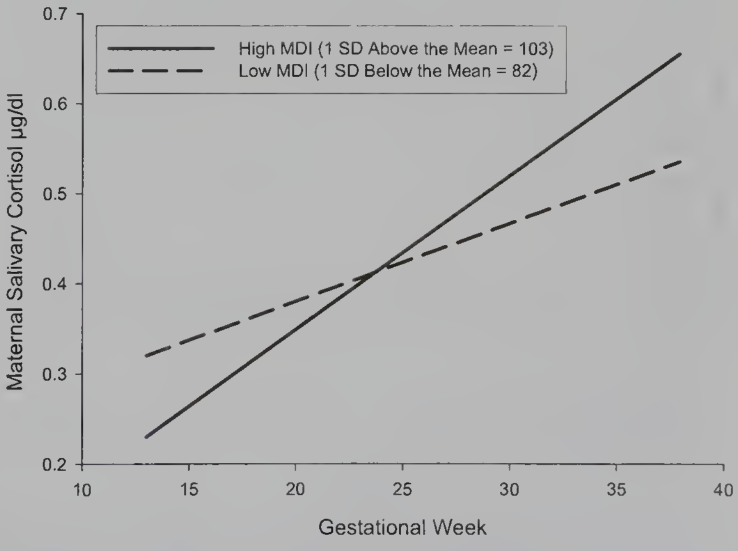

Figure 1. Infant performance on the Mental Developmental Index (MDI) at 12 months of age is associated with the trajectory of maternal cortisol across gestation. The top and bottom standard deviations for MDI are modeled with hierarchical linear modeling.

Note. Both maternal cortisol and MDI scores were analyzed as continuous variables. For graphing purposes, we have displayed the cortisol trajectory for mothers of infants with MDI scores 1 *SD* above or below the mean.

cognitive development, the slope of maternal cortisol across gestation was calculated for each woman. When the slope of maternal cortisol across pregnancy was added to the model it was demonstrated that cortisol slope was a stronger predictor of infant MDI ($\Delta R^2 = .06$, $\beta = .24$, $t = 2.8$, $p < .01$) than either early or late cortisol levels. Furthermore, after cortisol slope was entered into the model the effects of maternal cortisol early and late in pregnancy (intercepts at 13 or 38 weeks GA) were no longer significant ($ps > .3$). These data suggest that it is the profile of maternal cortisol across gestation that best predicts infant development.

Maternal Psychosocial Stress and Infant Development

A second set of HLM models were computed to examine associations between psychosocial indicators of maternal stress and infant development. Among all the measures of maternal distress (perceived stress, state anxiety, pregnancy-specific anxiety, and depression) only pregnancy-specific anxiety was significantly associated with infant development. Infant performance on the MDI was associated with both pregnancy-specific anxiety early in gestation and overall rate of change (shape of the curve) of pregnancy-specific anxiety across gestation ($t = 2.4$, $p < .05$). As shown in Figure 2, infants scoring low on the MDI had mothers with the profile of (a) high pregnancy-specific anxiety before 16 weeks GA ($ts = -2.6$ to -1.9, $ps < .05$) and (b) a steeper decline in pregnancy-specific anxiety through mid gestation (for rate of acceleration or instantaneous slope, $ts = 2.1$ to 2.9, $ps < .05$), such that no differences in level of pregnancy-specific anxiety were detected beyond 16 weeks of gestation. Maternal pregnancy-specific anxiety did not significantly predict whether infants were categorized as delayed using BSID criteria ($ps > .17$). Thirteen weeks GA was the time point at which level of pregnancy-specific anxiety most strongly predicted infant cognitive development. At 13 gestational weeks, a 5-point increase in PSA was associated with a 2-point decrease on the MDI. A stepwise regression was implemented to determine whether levels of pregnancy-specific anxiety at 13 weeks GA or the rate of change of pregnancy-specific anxiety over gestation best predicted infant scores on the MDI. After adjusting for covariates, overall rate of change of PSA was a stronger predictor of MDI than the 13-week GA intercept ($\Delta R^2 = .05$, $\beta = -.21$, $t = -2.4$, $p < .05$) and accounted for the variance associated with the 13-week GA intercept ($p = .24$).

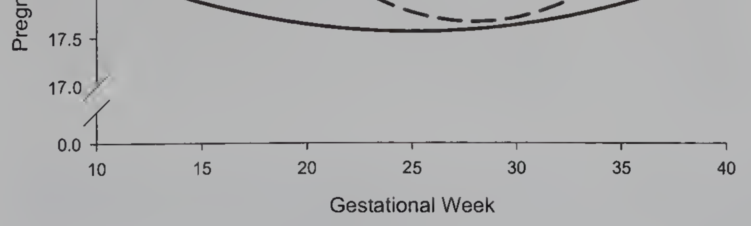

Figure 2. Elevated pregnancy specific anxiety early in gestation is associated with poorer performance on the Mental Developmental Index (MDI) at 12 months of age. The top and bottom standard deviations for MDI are modeled with hierarchical linear modeling.

Note. Both maternal pregnancy specific anxiety and MDI scores were analyzed as continuous variables. For graphing purposes, we have displayed the trajectory of pregnancy specific anxiety for mothers of infants with MDI scores 1 *SD* above or below the mean.

Influence of Maternal Psychological and Endocrine Factors on Infant Development

A hierarchical regression model was implemented to determine whether psychosocial (pregnancy-specific anxiety) and endocrine (cortisol) measures independently or jointly predicted portions of the variance in infant cognitive development. Furthermore, after adjusting for covariates, maternal cortisol measures (slope and intercepts, $\Delta R^2 = .07$, $p < .01$) and maternal PSA indicators (slope and intercept, $\Delta R^2 = .05$, $p < .05$) independently predicted MDI. Together these two measures accounted for 12% of the variance in infant performance on the MDI at 12 months of age.

Discussion

The current study provides further evidence that maternal cortisol and signals of maternal psychosocial stress play a role in the programming of the human fetus. Both maternal cortisol and maternal psychosocial stress (pregnancy-specific anxiety) were associated with the trajectory of infant development and influenced cognitive functioning at 1 year of age among healthy, full-term infants. Furthermore, the consequences of prenatal maternal stress were determined by the gestational period during which the fetus was exposed.

Prenatal Maternal Cortisol Influences Development

The present study suggests that prenatal maternal cortisol exerts a programming effect on human infant development. Maternal cortisol influenced the trajectory of infant development over the first postnatal year, resulting in differences in performance on the MDI at 12 months. Performance on the PDI was not associated with maternal cortisol.

As expected, maternal cortisol significantly increased across gestation. The pattern of prenatal maternal cortisol was associated with infant cognitive functioning. Prenatal maternal cortisol levels predicted the rate of infant cognitive development over the first postnatal year, resulting in significant differences in performance on the MDI at 12 months of age. Specifically, infants who scored high on the MDI at 12 months of age were exposed to (a) low concentrations of maternal cortisol in early pregnancy, (b) an accelerated trajectory of cortisol across gestation, and (c) high concentrations of cortisol toward the end of pregnancy. Thus, prenatal maternal cortisol had opposite effects on infant cognitive development depending on the timing of exposure. These findings are remarkably consistent with the role cortisol plays in the maturation of the human fetus. Early in pregnancy the fetus is protected from the naturally occurring increases in maternal cortisol by 11β-HSD2, an enzyme that converts cortisol into its inactive form. However, because 11β-HSD2 is only a partial barrier, excessive increases in maternal cortisol early in gestation will result in overexposure of the fetus with potentially detrimental consequences. In contrast, as pregnancy advances toward parturition exposure to elevated cortisol is necessary and beneficial for maturation of fetal organ systems, including the fetal lungs (Hacking et al., 2001). Fetal exposure to increased cortisol during the 3rd trimester is facilitated by the sharp decline in 11β-HSD2 activity which allows a greater proportion of maternal cortisol to cross the placental barrier (Giannopoulos et al., 1982; Murphy et al., 2006). The current data provide new evidence that the programming influence of maternal cortisol on the developing fetal nervous system is dependent on the timing of exposure. Exposure to elevated concentrations of cortisol early in gestation had deleterious effects on subsequent infant cognitive development, whereas exposure to elevated levels of maternal cortisol late in gestation was associated with enhanced performance on tasks assessing mental development. It is possible that effects were observed for the MDI and not PDI because areas of the brain that are critical for cognitive functioning such as the hippocampus and prefrontal cortex are more vulnerable to the effects of GCs (Lowy, 1994; Uno et al., 1994; Welberg, Seckl, & Holmes, 2001).

GCs, in addition to their critical role in lung maturation, play an important role in normal brain development and have been implicated in neuronal maturation and survival (Drake, Tang, & Nyirenda, 2007; Scaccianoce et al., 2001; Trejo et al., 2000). The association between increased concentrations of cortisol during the third trimester and improved cognitive functioning at 12 months of age is highly plausible given the role that GCs have been shown to play in regulating brain development in animal models. Although excessive prenatal administration of GCs causes both neural degeneration and impaired performance on cognitive tasks (Coe & Lubach, 2005; Uno et al., 1990; Uno et al., 1994), moderate increases in GCs facilitate brain development resulting in enhanced cognitive functioning (Casolini et al., 1997; Catalani et al., 2000; Scaccianoce et al., 2001). The current findings emphasize that within physiological limits during the prenatal period, the level of GCs associated with optimal development will be determined by the gestational period. Optimal development was observed in infants of mothers with low levels of maternal cortisol early and high levels late in pregnancy.

One other group that examined the effect of prenatal exposure to endogenous maternal cortisol for human infant cognitive development reported that elevated maternal cortisol during the third trimester was associated with poor performance on the MDI at 3 months of age (Huizink et al., 2003). The reason for the discrepancy between this report and the current study, where third trimester maternal cortisol was unrelated to 3-month BSID performance and positively related to 12-month BSID performance is unclear. There are, however, differences in the design of the two studies. The current investigation included longitudinal assessments of infants across the first postnatal year allowing us to evaluate the trajectory of infant cognitive development. Furthermore, at 3 months of age, performance on the BSID is highly influenced by infant behavioral state and later MDI scores are more stable than earlier scores (Bayley, 1993). The current study included a large sample of 125 mother–infant pairs and serial assessments of prenatal maternal cortisol levels at five distinct gestational periods. In this large sample with precise measures of maternal cortisol over the course of pregnancy, our results indicated that poor performance on the MDI at 12 months was associated with elevations in maternal cortisol early in pregnancy and not during the third trimester.

Prenatal Maternal Psychosocial Stress Influences Infant Development

Among all of the measures of prenatal maternal psychological distress (perceived stress, state anxiety, pregnancy-specific anxiety, and depression), only pregnancy-specific anxiety significantly predicted infant development. Maternal report of pregnancy-specific anxiety was highest early in pregnancy and declined as gestation advanced. Furthermore, both the level of pregnancy-specific anxiety early in gestation and the overall change in pregnancy-specific anxiety significantly predicted infant performance on the MDI, but not PDI, at 12 months of age. Pregnancy specific anxiety was not associated with infant development at earlier ages. A low infant MDI score at 12 months of age was associated with the maternal profile of high pregnancy-specific anxiety before 16 weeks GA and a steeper decrease in pregnancy-specific anxiety through mid gestation, at which point pregnancy-specific anxiety was not associated with infant development. It may be surprising that a steeper decline in pregnancy-specific anxiety was associated with poorer infant scores on the MDI. It is likely, however, that the steeper decline in pregnancy-specific anxiety reflects higher initial values; levels of pregnancy-specific anxiety did not differ later in gestation. It is not surprising that pregnancy relates stress changes across gestation. The stimuli that lead to pregnancy-specific stress appraisals are different early in gestation (e.g., fear of miscarriage) as compared to late in gestation (e.g., concern about labor and delivery). Pregnancy anxiety was not measured prior to 13 weeks GA and thus it remains possible that pregnancy anxiety earlier in pregnancy would have a greater effect. Further research is needed to better understand the way that pregnancy-specific stress changes across gestation as well as how pregnancy-specific stress is different from other types of stress. Importantly, the mother's pregnancy-specific anxiety predicted infant development even after controlling for actual medical risk and postnatal maternal stress. These data suggest that (a) signals of maternal psychosocial stress during the prenatal period may be transmitted to the fetus and have programming consequences for development, (b) the fetus is more vulnerable to the effects of these signals early in gestation, and (c) maternal stress related to pregnancy may have more profound implications for the fetus as compared to generalized maternal distress.

The finding that pregnancy-specific anxiety and not generalized distress measures predicts infant outcomes suggests that stress related to events, beliefs, or fears proximal to pregnancy are both novel and more relevant to the pregnant woman and therefore more consequential to the fetus and that this measure detects unique emotional distress. In contrast to the three generalized distress measures that evaluate stress related to generalized worry, daily hassles, and negative mood, the PSA scale evaluates maternal stress that is directly related to her pregnancy including concern about the health of her baby, fear of miscarriage, and worry about the development of pregnancy-related medical problems. Accumulating evidence indicates that that measures of pregnancy-specific anxiety are better predictors of shortened gestation (Roesch et al., 2004), fetal behavior (DiPietro et al., 2002), and infant outcomes (DiPietro et al., 2006; Huizink et al., 2003) than measures of generalized maternal distress. Overall, our finding that pregnancy-specific anxiety, but not generalized distress, was associated with impairments in infant cognitive development is consistent with these studies. The variability among studies relying on self-report of generalized maternal stress (Brouwers et al., 2001; DiPietro et al., 2006; Huizink et al., 2003; Van den Bergh, 1990) may be due to fact that these measures do not capture maternal stress related to the well being of her developing fetus that is unique to pregnancy. Two published studies examined the association between pregnancy-specific anxiety and infant cognitive development and found that elevated pregnancy-specific anxiety during the third trimester predicted poorer performance on tasks assessing infant development (DiPietro et al., 2006; Huizink et al., 2003). Although the effect of timing differed between our study and the two other published studies, our findings are consistent with evidence that the fetus is more vulnerable to maternal stress early in gestation (Mueller & Bale, 2007; Schneider et al., 1999). Further, we have found that elevated pregnancy-specific anxiety early in gestation is associated with brain development in childhood (Buss et al., in press).

Prenatal Maternal Stress Is Associated With the Trajectory of Infant Development

The current findings indicate that while prenatal exposure to maternal stress and stress hormones predict infant development, significant associations do not emerge until 12 months of age. Prenatal maternal cortisol levels were, however, associated with the trajectory of infant development over the first postnatal year. Individual patterns of low maternal cortisol early and high maternal cortisol late in pregnancy predicted an accelerated trajectory of infant cognitive development over the first postnatal year, resulting in improved performance on the MDI at 12 months. It is not clear why significant differences in performance on the MDI did not emerge until 12 months of age. During the prenatal period organs and organ systems are forming and thus are especially vulnerable to both organizing and disorganizing influences. Disruption at this early stage of development has the potential to alter developmental trajectories, resulting in developmental impairments that only emerge as that capacity develops. Thus, as cognitive functions come "on line" we may begin to detect delays that were not apparent previously. Consistent with this hypothesis there is evidence from experimental studies with rodents that exposure to early life stress can have consequences for cognitive functioning that are not observable until adulthood (Brunson et al., 2005) as well as from human observational studies associating size at birth with adult health outcomes (Barker, 1998, 2002). Alternatively, it is possible that the lack of differences at 3 and 6 months may be due to limitations in our ability to evaluate children at these young ages.

Postnatal Influences on Development

There is strong evidence across a wide range of species that early postnatal experiences influence the development of individual differences (Coplan et al., 1996; Dawson & Ashman, 2000; Levine, 1957). Maternal stress, anxiety, and depression during infancy have pervasive influences on development including enhanced stress reactivity, poor emotional regulation, and impaired cognitive development (Coghill, Caplan, Alexandra, Robson, & Kumar, 1986; Dawson & Ashman, 2000; Essex, Klein, Cho, & Kalin, 2002; Kaplan, Bachorowski, Smoski, & Hudenko, 2002). It is important to note the observed effects of prenatal exposure to maternal stress on infant development were independent of postnatal maternal psychological distress (anxiety, stress, and depression) and parenting-specific stress evaluated at 3, 6, or 12 months. Furthermore, the effects of prenatal stress were observed in our full-term cohort and were not explained by sociodemographic factors including household income, maternal education, age, race, or marital status or to maternal pregnancy-related medical risk factors. Our findings that prenatal maternal stress measures were significantly associated with cognitive development in full-term infants, and that this association was not mediated or moderated by relevant postnatal factors, add strong support to the argument that prenatal experiences and exposures have a significant role in shaping developmental outcomes.

Programming Influences of Prenatal Maternal Stress

The current findings in a healthy sample of full-term infants, demonstrate that both psychological (pregnancy-specific anxiety) and endocrine (cortisol) indicators of maternal stress are associated with poorer performance on the MDI of the BSID at 1 year of age. For both psychosocial and endocrine indicators of stress, timing of exposure was critical. Optimal performance on the MDI at 12 months of age was observed in infants of mothers with low levels of cortisol early in pregnancy and high levels near term. Despite the finding that fetal exposure early in pregnancy to maternal cortisol and pregnancy-specific anxiety had similar effects on infant mental development, these two measures were not correlated and they exerted independent influences on development. This finding is consistent with the majority of published studies that have failed to discover a significant relation between maternal psychological state and maternal cortisol during pregnancy (Davis et al., 2007; McCool & Susman, 1994; Petraglia et al., 2001; de Weerth & Buitelaar, 2005). Future research will have to examine other stress responsive hormones, as well as vascular or immune pathways that could be mechanisms by which increases in maternal psychosocial stress might affect the fetus.

Limitations

First, because this study relied on naturally occurring variations in maternal cortisol, rather than experimental manipulations, it is difficult to separate the effects of cortisol from the consequences of other factors that might contribute to this association such as components of the postnatal environment including postpartum depression or maternal stress or from shared genetic effects. In the current study, however, postpartum psychological state was not associated with infant development, and adjusting for postpartum maternal psychological state did not alter the relation between prenatal maternal stress measures and infant cognitive development, supporting our conclusion that prenatal exposures were responsible for this association. Furthermore, the current findings are consistent with animal models where random assignment is possible (e.g., Catalani et al., 2002; Weinstock, 2001) as well as recent human studies that have evaluated the consequences for development of randomly occurring stressful events, such as natural disasters (Laplante et al., 2004; Yehuda et al., 2005). Second, the current study included a low-risk sample of women with healthy, full-term pregnancies. It is probable that examination of women experiencing more severe stress or who have clinically significant psychopathology would reveal more profound programming influences on developmental outcomes. Third, maternal cortisol is an indirect measure of fetal exposure. However, there is evidence with human fetuses documenting that maternal and fetal cortisol levels are significantly correlated (Gitau et al., 1998; Gitau et al., 2001).

Conclusions

Studies from animal models have demonstrated that early life environmental factors, including exposure to maternal stress and stress hormones, can cause structural and functional changes to the developing nervous system that persist throughout the lifespan. This study is among the first to evaluate the effects of endocrine and psychosocial indicators of prenatal maternal stress for infant development. Data indicate that both endocrine and pregnancy-specific psychosocial indicators of stress changed over the course of gestation and that both independently predicted infant cognitive development at 1 year of age. These effects were strongly dependent on the timing of exposure and could not be accounted for by postnatal indicators of maternal distress. Elevated levels of maternal psychosocial stress and maternal cortisol early in gestation were associated with poorer cognitive functioning at 1 year of age. In contrast, later in gestation elevated maternal cortisol was associated with improved performance on the MDI at 1 year. The current study provides new evidence that prenatal exposure to maternal cortisol and maternal psychosocial stress exerts programming effects on the fetus with persisting consequences for infant behavior. During the prenatal period, the mother's physiology directly affects the fetus and has the opportunity to shape developmental trajectories. It may be for this reason that prenatal factors exerted a stronger influence on MDI performance at 1 year as compared to more proximal maternal factors. It is our intention to continue to follow this cohort to determine if there is a persisting influence of prenatal stress on other domains of functioning including emotional regulation and whether these effects persist to later development.

Mothers' Antenatal Depression and Their Children's Antisocial Outcomes

King's College London

Cerith S. Waters and Oliver Perra
Cardiff University

Deborah Sharp
University of Bristol

Interviews of 120 British adolescents and their parents (80% of a random sample of antenatal patients drawn from a representative urban population and followed longitudinally) revealed that 40 (33%) had been arrested and/or had a diagnosis of *DSM–IV* conduct disorder by 16 years of age; of those, 18 (45%) had committed violent acts. Depression in pregnancy significantly predicted violence in adolescence, even after controlling for the family environment, the child's later exposure to maternal depression, the mother's smoking and drinking during pregnancy, and parents' antisocial behavior. Mothers with a history of conduct problems were at elevated risk to become depressed in pregnancy, and the offspring of depressed women had a greater chance of becoming violent by age 16.

The aim of our study was to examine links between exposure to maternal depression in pregnancy and antisocial outcomes in a longitudinal sample of British children who were studied at intervals until the age of 16. It has been shown that the mother's mental health problems in pregnancy predict disruptive behavior disorders in offspring. In particular, the mother's symptoms of anxiety predict behavioral problems (O'Connor, Heron, Golding, Beveridge, & Glover, 2002) and attention deficit hyperactivity disorder (Van den Bergh & Marcoen, 2004; Van den Bergh, Mennes, et al., 2005; Van den Bergh, Mulder, Mennes, & Glover, 2005; Van den Bergh et al., 2006). In a large Finnish cohort, mothers' reports of depression during pregnancy predicted antisocial behavior in their adult offspring 30 years later (Maki et al., 2003). In this study we concentrate attention on the more prevalent clinical disorder, depression, while simultaneously controlling for the level of mothers' anxiety symptoms in pregnancy.

Although these studies have found evidence for an association between mothers' mental health problems in pregnancy and children's outcomes, it is not clear whether that association reflects a direct effect of the mother's mental state on the fetus or whether it is accounted for by other social and biological processes. Several plausible hypotheses can be generated to account for these links between antenatal exposure to maternal depression and antisocial outcomes. The association could be explained by: (a) *direct effects on the developing fetus* from the biological correlates of the mothers' symptoms; (b) *the association of depression in pregnancy with more general measures of environmental adversity*, which are well-known predictors of antisocial behavior; (c) *re-exposure to the maternal depression*, whereby infants who are exposed in pregnancy are at elevated risk for re-exposure and consequent disruption of the postnatal environment; (d) *indirect effects of antenatal depression on the developing fetus* mediated by mothers' smoking, drinking, and drug taking in pregnancy; and (e) *parents' antisocial behavior*, as women who experience depression in pregnancy may also be at genetic risk for antisocial behavior and may transmit both risks to offspring. There is evidence bearing on each of these hypotheses.

The SLCDS has been funded by the Medical Research Council UK Project Grants G89292999N and G9539876N awarded to the late Channi Kumar, Deborah Sharp, and Dale Hay; the Psychiatry Research Trust; and the South West G.P. Trust. The present data coding and analyses were partially supported by an Economic and Social Research Council studentship to Cerith S. Waters and Medical Research Council UK Programme Grant GO400086. We thank Helen Allen for her contribution to the retention of the sample, and the families who participated in the study for 16 years.

Evidence for the Alternative Hypotheses

Hypothesis 1: The mother's depression in pregnancy has direct effects on the developing fetus. Conduct problems, especially those that emerge in early childhood, are linked to neurobiological deficits (e.g., Raine et al., 2005), which are in turn associated with risk factors in the antenatal environment (van Goozen, Fairchild, Snoek, & Harold, 2007; Raine, 2002). Possible mechanisms whereby mothers' symptoms of mental illness affect their children include disruption of normal development of the hypothalamic-pituitary-adrenal (HPA) axis (e.g., Lundy et al., 1999; Talge et al., 2007; van Goozen et al., 2007) and effects of gestational stress on fetal growth (e.g., Borders, Grobman, Amsden, & Holl, 2007; Rahman, Bunn, Lovel, & Creed, 2007). Our aim in this study was not to test specific hypotheses about potential mechanisms but merely to establish whether there was evidence for an association with antenatal depression, once the alternative hypotheses had been tested.

Hypothesis 2: The link between antenatal symptoms and antisocial behavior is explained by preexisting environmental adversity. Antisocial behavior flourishes in adverse social environments. For example, children's aggression has been linked to socioeconomic adversity (e.g., Keenan & Shaw, 1994), exposure to adult maltreatment (e.g., Dodge, Bates, & Pettit, 1990), and high levels of violence in the community (e.g., Kupersmidt, Griesler, DeRosier, Patterson, & Davis, 1995). One well-known marker of general environmental adversity is teenage parenthood, which predicts antisocial behavior (Jaffee, Caspi, Moffitt, Belsky, & Silva, 2001) and is also associated with the mother's marital status and her history of depressive illness (Romano, Zoccolillo, & Paquette, 2006). It is possible that the effects of antenatal depression disappear when environmental adversity is taken into account.

Hypothesis 3: The link between antenatal depression and antisocial outcomes is explained by re-exposure to maternal depression. Developmental theorists have long argued that any test of early experience effects —that is, analyses of the impact of deprivation and stimulation before and immediately after birth— must be conducted with reference to individuals' experiences later in life, and the present circumstances under which they are being assessed (Cairns, 1979; Rutter, 1972; Solomon & Lessac, 1968). Thus, when trying to explain why antenatal depression predicts disruptive behavior in offspring, it is important to note that depression is a lifelong, episodic illness, and the child is likely to be re-exposed. Exposure to maternal depression during fetal life predicts later exposure postpartum (O'Hara, 1997), and postpartum depression predicts subsequent episodes in later childhood and adolescence (Halligan, Murray, Martins, & Cooper, 2006).

The mother's chronic depressive illness has been linked to children's emotional and behavioral problems (Campbell & Cohn, 1997). Maternal depression during childhood is a strong predictor of children's conduct symptoms, even when the mother's antisocial behavior is taken into account (Kim-Cohen, Moffitt, Taylor, Pawlby, & Caspi, 2005). It is therefore possible that any effects of antenatal depression are explained by the child's later exposure to the mother's illness.

Hypothesis 4: The mother's illness has indirect effects on the developing fetus that are mediated by her substance use in pregnancy. Smoking, alcohol, and drug use in pregnancy are associated with deleterious outcomes for the fetus and the child (e.g., Carvalho De Moraes Barros, et al., 2006; Mathews, Menaker, & MacDorman, 2003; Maughan, Taylor, Taylor, Butler, & Bynner, 2001). To the extent that depressed women are more likely to drink, smoke, and take legal and illegal drugs in pregnancy, their offspring are more likely to be exposed to these antenatal insults, which are thought to exert direct influence on the developing fetus.

Hypothesis 5: Many children whose mothers experience depression in pregnancy are already at familial risk for antisocial behavior. There is considerable evidence for genetic as well as environmental transmission of risk for antisocial behavior from parent to child (Moffitt, 2005), and so it is important to consider whether the association between antenatal depression and children's antisocial outcomes can be explained by parents' own antisocial tendencies. Two important issues to consider are the *co-occurrence* of the mother's depressive illness and her history of conduct disorder (CD), and *assortative mating* between antisocial women and men.

With respect to the first issue, women with an antisocial history are more likely than other mothers to expose their offspring to depression in pregnancy, because CD is often associated with depression (Romano et al., 2006; Zoccolillo, Meyers, & Assiter, 1997). Girls who have shown conduct problems in childhood are likely to experience depression in adolescence and adulthood (Rutter, Giller, & Hagell, 1998) and are at special risk for depression during pregnancy and the months after childbirth (Cassidy, Zoccolillo, & Hughes, 1996; Romano et al., 2006). Thus, a substantial proportion of women who experience depression during pregnancy have a past history of antisocial behavior.

Second, with respect to the issue of assortative mating, the offspring of women with a history of CD and current depression may also be at genetic risk through processes of paternal transmission. Antisocial women may often have antisocial partners (Galbaud du Fort, Boothroyd, Bland, Newman, & Kakuma, 2002; Krueger, Moffitt, Caspi, Bleske, & Silva, 1998), and the presence of paternal as well as maternal antisocial tendencies would increase the risk for the child. Thus, it is important to control for antisocial behavior in both biological parents.

Aim of the Study: Charting Cumulative Risk for Antisocial Behavior From Pregnancy to 16 Years

In highlighting these alternative explanations of a link between the mother's depression in pregnancy and her child's antisocial behavior, it immediately becomes clear that the different processes under investigation are not mutually exclusive. Indeed, the evidence shows that the children of mothers who are depressed in pregnancy may also be exposed to a cumulative sequence of risk factors, including the pregnant woman's anxiety symptoms, her use of substances during pregnancy, and her subsequent episodes of depressive illness. These cumulative risks associated with antenatal depression would be further exacerbated by her antisocial tendencies, the father's antisocial behavior, and general environmental adversity throughout the child's lifetime. To determine whether depression in pregnancy has direct effects, or is explained by the other risks that accumulate over the child's life, more detailed descriptive information is needed, preferably from a longitudinal sample that was first assessed in pregnancy.

Therefore, the aim of our study was to describe such accumulation of risks for antisocial behavior from the mother's pregnancy to 16 years of age in a population of British children who reside in relatively disadvantaged urban communities and are therefore already at general environmental risk for antisocial behavior, psychopathology, and poor educational and occupational outcomes. The South London Child Development Study (SLCDS) is an ongoing longitudinal study of families in two areas of South London. The original purpose of the study was to identify the environmental predictors of women's physical and mental health in pregnancy and the first year postpartum (Sharp, 1993). Subsequent follow-up assessments at 4, 11, and 16 years postpartum have tested whether the mother's perinatal illness increased the children's risk for cognitive, emotional, and behavioral problems (e.g., Hay et al., 2001, Hay, Pawlby, Angold, Harold, & Sharp, 2003; Pawlby, Hay, Sharp, Waters, & O'Keane, 2009). The SLCDS thus provides an opportunity to chart the pathway of cumulative risk from fetal life to adolescence, in a population that has been exposed to many of the community influences that promote antisocial behavior.

Within these urban communities, some families (approximately 10%) are well educated and affluent, but most are working-class families who have experienced some economic disadvantage. Examination of cumulative risk in this urban sample controls for variation in environmental context (e.g., urban–rural differences) and focuses attention on the psychological and behavioral processes that explain why some but certainly not all of the children in these communities follow pathways toward antisocial behavior.

Prediction of Violent Versus Nonviolent Antisocial Behavior

We aim to determine whether antenatal depression has different effects on different domains of antisocial behavior. It is possible that a combination of antenatal risk factors and periodically disrupted postnatal environments contribute to the development of violence in particular. Loeber et al. (1993) proposed that there is a distinct developmental pathway toward overt physical aggression and violence, as distinguished from covert antisocial acts or nonviolent conflict with authority figures. Serious violence peaks in adolescence and young adulthood, but individual differences in violent tendencies may nonetheless be influenced by earlier risk factors. Thus, in the present study, we examine the effects of depression in pregnancy on violent and nonviolent antisocial behavior in adolescence while controlling for general environmental adversity, cumulative exposure to maternal mental illness, substance use in pregnancy, and parents' antisocial behavior.

Method

The Families

A random sample of 178 women was drawn from records of consecutive antenatal patients who attended two National Health Service (NHS) general medical practices in South London in 1986 (Sharp, 1993). In the United Kingdom, 96% of the population is registered with the NHS (Hannaford, Smith, & Eliot, 2006). Only 0.5% of births in the United Kingdom take place in private hospitals (NHS, 2004/2005). Therefore, virtually all pregnant women in the two geographical catchment areas were registered for antenatal care at these two NHS medical practices, and this sampling frame permitted recruitment of a truly random sample from a representative population of infants born in these areas during 1 year of recruitment.

Of the 178 women in the random sample at the beginning of their pregnancies, 9 suffered miscarriages, intrauterine death, or stillbirth; 7 moved out of the area and at that point were excluded from the sample; 1 infant was taken into the care of social services and researchers' access was denied; and 10 declined to participate further in the study. Thus, the follow-up study of the children was based on the remaining $N = 151$ cases (89% of the random sample). At 16 years, 137 of the 151 families (91%) participated in the study. This study focuses on 120 families (80% of 151 assessed postpartum) for whom complete information was available on all variables needed to test the study hypotheses.

Characteristics of the participants with complete data at age 16 are summarized in Table 1. Compared to national norms, the sample had a higher proportion of working-class families and families from ethnic minorities (UK Office for National Statistics, 2006). Based on the 2001–2002 data collected throughout England, the deprivation scores of the two South London communities from which the random sample was drawn ranked on the 6th and 11th percentiles, where a lower rank indicates greater deprivation. The sample of $N = 120$ cases with complete data did not differ significantly from the cases assessed postpartum ($N = 151$) with respect to social class, mothers' marital status at birth, mother's age at first birth, parents' ethnic origin, the infant's birth weight, and the proportion of firstborns.

All phases of the study were approved by the Ethics Committee of the Institute of Psychiatry, King's College London. After complete description of all procedures, written informed consent was obtained from mothers and at 16 years from their adolescent offspring.

Procedure

Pregnancy and the first postnatal year. Two doctors, one from each practice, interviewed the mothers, who were not their patients, twice during pregnancy, between 14 and 20 weeks and at 36 weeks, and twice during the first postnatal year, at 3 and at 12 months.

Table 1
Characteristics of the Sample at 16 Years Postpartum (N = 120)

Variable	Description
Mother's age at birth	$M = 26.7$, $SD = 5.0$ (range = 17–44)
Mother's age at first birth	$M = 23.8$, $SD = 4.6$ (range = 17–37)
Marital status at birth	65% married, 28% cohabiting, 7% single
Social class	88% working class
Maternal education	72% basic qualifications or higher
Marital status at age 16	59% married (87% to biological father) 13% cohabiting (33% to biological father) 28% single parent household
Parent in household at 16	54% two biological parents 39% biological mother 5% biological father 2% no biological parent (living independently, $N = 1$; under supervision of Social Services, $N = 1$)
Child's sex	55% female
Child's birth order	48% firstborn
Child's ethnicity	72% White British, 6% White, non-British, 22% Other (Caribbean, African, South Asian, East Asian, mixed)
Child's age at assessment	$M = 16.3$ years, $SD = 0.2$ (range = 16–17.3)

Note. *N*s vary slightly (117–120) because of missing data on some variables.

Fourth, 11th, and 16th birthdays. Families were visited at home at 4, 11, and 16 years postpartum, and at 11 years the children were seen at school. At each time point mothers provided sociodemographic information, current and retrospective to the last visit, to interviewers who were unaware of the information collected at previous visits. Parents (in most cases, the biological mother) and children were interviewed at 11 and 16 by different researchers.

Measures

Maternal psychopathology. At both points in pregnancy and at 3 and 12 months postpartum, an assessment was made of the women's current mental state, using the Clinical Interview Schedule (CIS) to generate ICD-9 diagnoses of depression and anxiety (Goldberg, Cooper, Eastwood, Kedward, & Shepherd, 1970). The overall agreement of the reported symptoms on the CIS from the tape-recorded interviews, given as a weighted kappa coefficient, was .80. Mothers completed the Leeds

Anxiety Scale (Snaith, Bridge, & Hamilton, 1971) twice, in the second and third trimesters of pregnancy. The Leeds scale scores at each time point were averaged to provide a composite measure of symptoms of anxiety in pregnancy.

At 4, 11, and 16 years postpartum, mothers were interviewed about their current mental states and experience of symptoms retrospective to the last assessment point, using the Schedule of Affective Disorders and Schizophrenia (SADS–L; Spitzer, Endicott, & Robins, 1978). Diagnoses were made in consultation with the lead psychiatrist on the team, using Research Diagnostic Criteria (RDC).

Depression in pregnancy was defined by the combined ICD diagnoses from the second and third trimester interviews; if the woman had met ICD criteria for depression at either time, she was judged to have experienced antenatal depression. Postpartum depression was defined by the ICD diagnosis of depression at 3 months postpartum. ICD criteria were also used to diagnose depression at 12 months postpartum.

The current and "retrospective to last visit" data were used to assess the occurrence of maternal depression over the child's lifetime. Two additional variables were created to measure the children's exposure to maternal depression in early childhood (between 1 and 4 years of age) and later childhood (between 4 and 11 years of age). An ordinal variable of the number of time periods in which women were diagnosed with depression was then computed.

Sociodemographic risk factors. Characteristics of the family environment were assessed by interview at all time points (see Table 1). Dichotomous measures of risk factors in the family environment were then computed: (a) mother's *social class*, based on occupation (Goldthorpe & Hope, 1974), dichotomized into working versus middle or upper class; (b) *maternal education*, dichotomized into no qualifications versus basic qualifications or higher; (c) self-reported *cultural background*, dichotomized into White British versus other ethnic identity; (d) *mother's age at the birth of the index child*, dichotomized as teenager (19 years of age and under) versus older; (e) *mother's age at the birth of her first child*, dichotomized as teenager (19 years of age and under) versus older; (f) *mother's marital status* at the child's birth (married vs. cohabiting or single/divorced/widowed); and (g) *two-parent family structure* at the child's birth (married/cohabiting vs. single/divorced/widowed).

The mother's intellectual ability. During the home visit at 4 years, four subtests (vocabulary, arithmetic, similarities, and block design) of the Wechsler Adult Intelligence Scale (WAIS; Wechsler, 1981) were administered to the mothers and scored to a formula that takes into account correlation with the full WAIS in terms of the subtests' reliability and age-scaled scores (Brooker & Cyr, 1986). The subtests were used again at the 11- or 16-year assessment to assess those mothers who had not been seen since the first postnatal year.

Measures of mothers' smoking and drinking during pregnancy. During the second- and third-trimester interviews, mothers reported the number of cigarettes smoked per day and units of alcohol drunk per week. Composite measures of fetal exposure to cigarette smoking and alcohol were constructed by averaging the scores reported at each interview.

Mothers' antisocial behavior. Mothers' history of arrest was obtained from their interviews at 4, 11, and 16 years. At the 16-year visit, we obtained mothers' retrospective reports of their own conduct symptoms before the age of 15, using the antisocial personality disorder section of the SADS–L. All women were asked about juvenile conduct symptoms, whether or not they screened in as possible cases of antisocial personality disorder. A 10-item scale was constructed, summing women's reports of truancy, expulsion from school, rule breaking, stealing, lying, running away, vandalism, underage alcohol use, underage sex, and juvenile arrest (Cronbach's $\alpha = .75$).

Biological fathers' history of arrest. Mothers reported on the biological fathers' history of arrest at the 11- and/or 16-year interviews. Previous research has demonstrated the reliability of mothers' reports about their partners' antisocial behavior (Caspi et al., 2001). In five cases where the mother did not have custody of the child, the father was interviewed and reported on his own history of arrest.

Adolescents' antisocial behavior. At 11 and 16, parents and children were interviewed separately about the child's symptoms of clinical disorder, using the Child and Adolescent Psychiatric Assessment (CAPA; Angold et al., 1995). The CAPA is a psychiatric interview that elicits information about symptoms contributing to a wide range of *DSM–IV* (American Psychiatric Association, 1994) diagnoses. A 3-month "primary period" is used to ensure more accurate recall (Angold, Erkanli, Costello, & Rutter, 1996).

At 11 and 16 years, *DSM–IV* diagnoses and symptom scales were generated by computer algorithms, based on "combined reports," where a symptom is regarded as being present if either parent or child reports it. Diagnoses were made with reference to the functional impairment or incapacities section of the CAPA, which relates the symptoms to the adolescent's ability to function at a developmentally appropriate level in relationships with family, peers, and teachers, and in activities at school, home, and in the community. Diagnoses made using CAPA algorithms show acceptable levels of test–retest reliability (Angold & Costello, 2000).

For the purposes of this study, to identify youngsters with a history of antisocial activity, we focus on the *DSM–IV* diagnoses of CD based on parents' and adolescents' joint reports at ages 11 and 16 and the parents' and/or adolescents' reports of police contact up to the age of 16. A dichotomous measure of antisocial behavior was constructed, with adolescents judged to show antisocial tendencies if they had been arrested up to the age of 16 and/or been diagnosed with CD at age 11 and/or 16.

Violent antisocial behavior was defined in terms of the *DSM–IV* categorization of aggressive conduct symptoms (fighting, bullying, cruelty to people, theft with confrontation, and use of a weapon) and/or arrest for violent crimes (theft from a person, violent disorder, fighting, carrying an offensive weapon, assault, and actual bodily harm/grievous bodily harm). Antisocial adolescents were further categorized as showing violent behavior if they had shown at least one aggressive conduct symptom (in the context of the *DSM–IV* diagnosis of CD) and/or had been arrested for a violent crime.

Data Analysis

All variables were examined for psychometric properties and analyses appropriate to the scale of measurement were used. We first present univariate associations between depression in pregnancy and other risk factors, and between antisocial behavior and all risk factors (see Tables 3 and 4). Logistic regression models were then used to test the five alternative hypotheses regarding the association between depression in pregnancy and antisocial outcomes. We then tested whether depression in pregnancy predicted violent behavior in particular (see Table 5, Figure 1a–c). Subsequent Markov chain models were employed, using LEM 1.0 (Vermunt, 1997), to elucidate further the additive contribution of multiple risk factors to the prediction of violent behavior.

Results

Antisocial Outcomes

Incidence of arrests and DSM–IV *CD*. Forty of the 120 adolescents (33%) met criteria for clinically and socially significant antisocial behavior (see Table 2). Of the 40, 32 (88.9%) had been arrested before the age of 16 for a variety of violent and nonviolent offences (Table 2). Twenty (50%) had been diagnosed with CD at 11 and/or 16, 12 of whom had also been arrested. Adolescents who had been diagnosed with CD were significantly more likely than other children in the sample to be arrested, $\chi^2(1) = 13.64$, $p < .001$, odds ratio (OR) = 6.00 (95% confidence interval [CI] 2.16–16.64).

Of the 32 adolescents who had been arrested by age 16, 12 had committed offences involving violence against people: theft from a person, violent disorder, fighting, carrying an offensive weapon, assault, and actual bodily harm/grievous bodily harm (see Table 2). Of the 8 additional adolescents who had not been arrested, but who met *DSM–IV* criteria for CD, 6 had shown aggressive conduct symptoms. Thus, 18 adolescents were classified as having shown some evidence of violent antisocial behavior (15% of the sample, and 45% of those who were classified as antisocial at age 16).

Tests for sex differences in antisocial behavior. Twenty-two of 54 boys (40.7%) and 18 of 66 girls (27.3%) met criteria for antisocial behavior in adolescence, having been arrested or diagnosed with CD, using *DSM–IV* criteria. The sex difference was not significant. Further analyses revealed no significant sex differences in any measure of antisocial behavior. Sixteen boys (29.6%) and 16 girls (24.2%) had been arrested; 12 boys (22.2%) and 8 girls (12.1%) were diagnosed with CD at either 11 or 16. Eleven boys (20.4%) and 7 girls (10.6%) had engaged in violent antisocial behavior. In view of the absence of significant sex differences, subsequent analyses were undertaken on the whole sample.

Mothers' Experience of Mental Health Problems in Pregnancy

Thirty-eight women (31%) met ICD-9 diagnostic criteria for depression and 4 for an anxiety disorder during pregnancy, with 2 women being comorbid. Our analyses therefore focus on diagnostic caseness for the more prevalent disorder, depression, while controlling for anxiety symptoms as a continuous measure in the sample as a whole. Depressed women had significantly higher levels of anxiety symptoms in pregnancy, $M = 6.3$ ($SD = 3.4$) for depressed women versus $M = 4.3$ ($SD = 2.9$) for women who were not depressed, $t(118) = -3.27$, $p < .001$. The associations between depression in pregnancy and the other risk factors tested are summarized in Table 3.

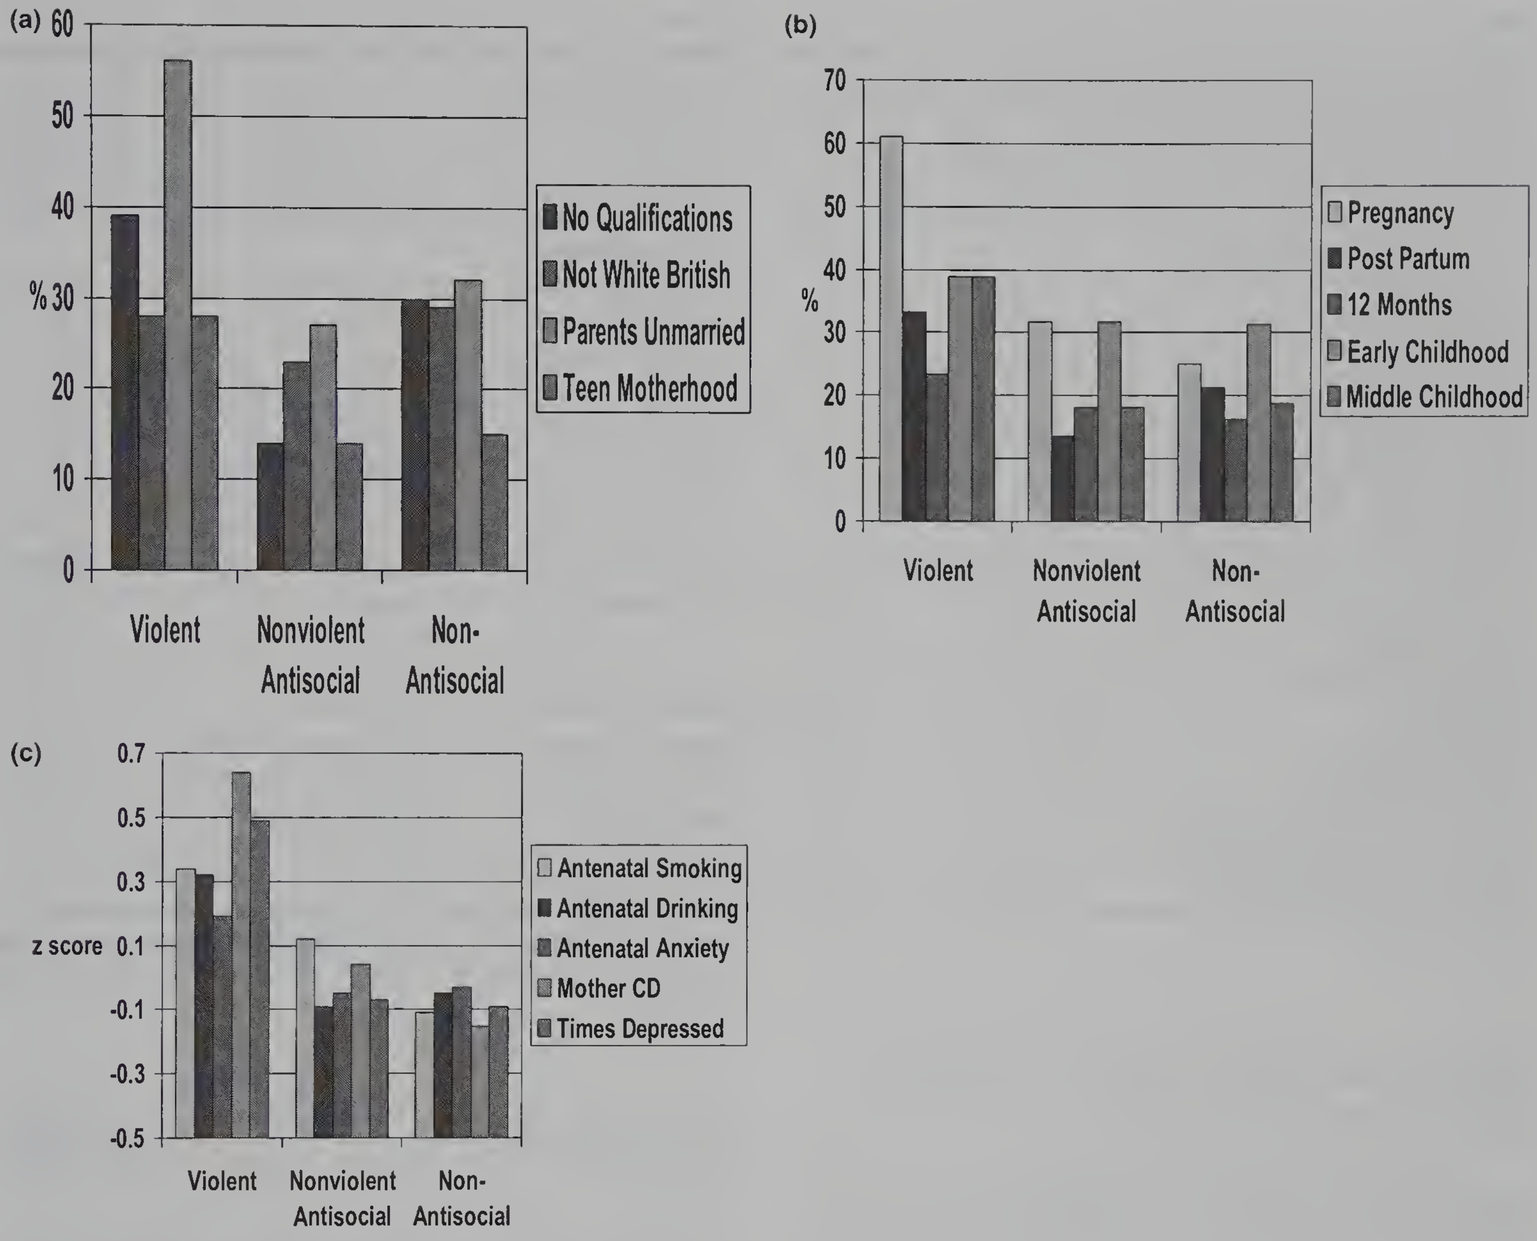

Figure 1. Prior environmental risk factors (a), exposure to maternal depression (b), and maternal risk factors (c) for violent, nonviolent antisocial, and non-antisocial adolescents.

Hypothesis 1: Antenatal Depression Has Direct Effects on Antisocial Behavior in Adolescence

The mother's ICD-9 caseness for depression in pregnancy was a significant predictor of antisocial behavior in adolescence. If mothers had not been depressed during pregnancy, 22 of 82 adolescent offspring (26.8%) showed antisocial behavior. In contrast, if mothers had been depressed in pregnancy, 18 of 38 adolescent offspring (47.4%) showed antisocial behavior, $\chi^2_{(1)} = 4.93$, $p < .03$, OR = 2.46 (95% CI 1.10–5.48). Furthermore, adolescents whose mothers had been depressed in pregnancy were at a fourfold risk for violence. When mothers had not been depressed in pregnancy, 7 of 82 adolescents (8.5%) had shown violence, as opposed to 11 of 38 adolescents (28.9%) whose mothers had been depressed at that time (see Table 5), $\chi^2(1) = 8.48$, $p < .01$, OR = 4.36 (95% CI 1.54–12.41).

Antisocial behavior in adolescence was not significantly associated with the mothers' reports of anxiety symptoms during pregnancy (see Table 4). There was no evidence for a timing effect. Anxiety symptoms in midpregnancy and in late pregnancy were both unrelated to antisocial behavior in adolescence. A logistic regression analysis revealed that the association between depression in pregnancy and antisocial behavior remained significant when controlling for anxiety symptoms in pregnancy, Wald statistic = 4.60, $p < .03$, OR = 2.51 (95% CI 1.08–5.83), as did the association between depression in pregnancy and violent behavior, Wald statistic = 6.91, $p < .01$, OR = 4.33 (95% CI 1.45–12.92).

Table 2

The Nature of Antisocial Activities Shown by the Adolescents (DSM–IV Conduct Disorder at 16 and/or Worst Offence for Which Arrested by 16; N = 40/120)

	N	%
DSM–IV conduct disorder at 11 or 16, no arrest	8	6.7
Shoplifting	6	5.0
Theft of property	1	0.8
Truancy	2	1.7
Fraud/intention to defraud	1	0.8
Rule breaking/underage drinking	1	0.8
Drug dealing/possession	1	0.8
Trespassing	2	1.7
Vandalism/damage to property	3	2.5
Joy riding	1	0.8
Fire setting/arson	1	0.8
Breaking and entering	1	0.8
Fighting[a]	6	5.0
Violent disorder	1	0.8
Theft from a person[a]	1	0.8
Possession of an offensive weapon[a]	2	1.7
Assault on a person (no injury)[a]	1	0.8
Actual/grievous bodily harm[a]	1	0.8

[a]Violent crimes.

Hypothesis 2: The Association Between Antenatal Depression and Antisocial Behavior Is Explained by Prior Environmental Adversity

Univariate analyses showed that, in these urban communities, depression in pregnancy was not significantly predicted by social class, cultural background, the mother's education, or the mother's IQ (see Table 3), but was more likely to occur if the mother was not legally married at the time of the child's birth, $\chi^2(1) = 3.74$, $p < .05$; if she had been a teenager at the time of the infant's birth, $\chi^2(1) = 3.77$, $p < .05$; and if she had been a teenager when she first entered into motherhood, at the birth of her first child, $\chi^2(1) = 6.04$, $p < .025$. However, the child's antisocial behavior was not predicted by any of these variables (see Table 4).

Violent adolescents did not differ significantly from other adolescents with respect to social class, maternal education, ethnicity, or maternal IQ, but were more likely to have been born to unmarried parents (cohabiting vs. married couples; none of the 8 adolescents born to single women was violent; see Table 5). When marital status was taken into account, depression in pregnancy remained a significant predictor of violent behavior, Wald statistic = 6.21, $p < .01$, OR = 3.87 (95% CI 1.34–11.20), and being born to unmarried parents was no longer significant.

Table 3

Associations Between Depression in Pregnancy and Other Potential Explanatory Variables

	Risk factor	Correlation
Antenatal mental health problems	Antenatal anxiety	.29***
Prior environmental adversity	Social class	.01
	Mother's education	.05
	Mother's IQ	−.14
	White British ethnicity	.02
	Parents unmarried	.18*
	One-parent family	.07
	Mother teenager this birth	.12*
	Mother teen at first birth	.21**
Child's re-exposure to depression	3 months postpartum	.33***
	12 months	.24**
	Years 1–4	.22*
	Years 4–11	.33***
Antenatal substance use	Cigarettes/day	.17†
	Units of alcohol/week	.02
Parents' antisocial behavior	Maternal CD symptoms	.20*
	Mother arrests	.10
	Father arrests	.12

Note. Kappa coefficients are reported for associations with nominal variables, point biserial coefficients for associations with continuous variables. IQ = intelligence quotient; CD = conduct disorder.

$^\dagger p < .10$. $^* p < .05$. $^{**} p < .01$. $^{***} p < .001$.

Hypothesis 3: The Effect of Depression in Pregnancy Is Explained by Later Exposure to the Mother's Depressive Illness

Mothers who were depressed in pregnancy were highly likely to become depressed again (see Table 3). Of the 38 women who were depressed in pregnancy, 16 (42.1%) were depressed postpartum, and 17 others (44.7%) became depressed at a later point in the child's life. All but 5 of the 38 women who had been depressed in pregnancy had at least one subsequent episode.

However, antisocial behavior was not associated with maternal depression at later points in the child's development, either in the months following childbirth, at 12 months of age, in early childhood, or in the primary school years (see Table 4). When depression at 3 months postpartum was included in the regression model, it was not significantly associated with antisocial behavior in adolescence, and depression during pregnancy remained a significant predictor of antisocial behavior. Nor was the effect of antenatal depression explained by the mother's subsequent depression, either at 12 months, in early childhood or the primary school years. Furthermore, antisocial adolescents did not differ significantly

Table 4

Exposure to Depression in Pregnancy and Other Risk Factors for Adolescents Who Had or Had Not Been Arrested or Diagnosed With Conduct Disorder (CD) at Age 11 and/or 16

	Risk factor	Antisocial (*N* = 40)	Not antisocial (*N* = 80)

*$p < .05$. **$p < .01$.

from other adolescents in the number of time periods during which they had been exposed to maternal depression, *Mdn* = 1 (range = 0–4) for the antisocial adolescents versus *Mdn* = 1 (range = 0–4) for the others, which was not a significant difference by the Mann–Whitney test, $z = -1.55$, *ns*.

Violent adolescents were somewhat more likely to have been exposed to the mother's depression between 4 and 11 years of age, $\chi^2(1) = 3.70$, $p < .054$ (see Table 5); the two groups did not differ with respect to exposure at other points in the child's lifetime. When exposure to maternal depression between 4 and 11 years was taken into account, depression in pregnancy remained a significant predictor of violence, Wald statistic = 5.37, $p < .02$, OR = 3.70 (95% CI 1.22–11.16), and the mother's depression in the middle childhood years no longer was significant. Adolescents who were violent had been exposed to maternal depression in a greater number of time periods, *Mdn* = 2 (range = 0–4) for violent youngsters versus *Mdn* = 1 (range = 0–4) for nonviolent ones, $z = -2.51$, $p < .01$ by the Mann–Whitney *U* test; however, this did not explain the effect of antenatal depression.

Hypothesis 4: The Effect of Depression in Pregnancy Is Explained by Mothers' Smoking and Drinking During Pregnancy

Women who were depressed in pregnancy smoked more cigarettes than women who were not depressed, *M* = 6.2 (*SD* = 7.1) versus *M* = 3.6 (*SD* = 7.2) for the depressed and nondepressed women, respectively, but the difference only approached statistical significance, $t(118) = -1.91$, $p < .06$. Depressed and nondepressed women did not differ in their reported use of alcohol during pregnancy, *M* = 1.0 (*SD* = 2.4) versus *M* = 0.9 (*SD* = 1.7), respectively.

Antenatal exposure to cigarette smoking and alcohol did not predict antisocial outcomes for the children. The mothers of antisocial teenagers had not smoked significantly more cigarettes per day and had not drunk significantly more units of alcohol per week, than other mothers in the sample (see Table 4). Similarly, the mothers of adolescents who had shown violent behavior had not been significantly more likely to smoke or drink alcohol in pregnancy (see Table 5). When fetal exposure to cigarette smoking and alcohol was taken into account, depression in pregnancy continued to predict antisocial behavior, Wald statistic = 3.83, $p < .05$, OR = 2.26 (95% CI 1.00–5.13), and violent behavior in particular, Wald statistic = 6.62, $p < .01$, OR = 4.07 (95% CI 1.40–11.84).

Hypothesis 5: The Association Between Depression in Pregnancy and Antisocial Behavior Is Explained by Associations With Biological Parents' Antisocial Behavior

To the extent that women's depression is often associated with a history of CD, and both disorders are influenced by genetic as well as environmental factors, the children of depressed mothers are at both genetic and environmental risk for antisocial outcomes. Furthermore, due to processes of assortative mating, children of depressed mothers who are also antisocial may be at genetic as well as environmental risk for antisocial behavior through processes of paternal as well as maternal transmission. We examined the evidence for each of these possibilities.

Associations between the mother's depression in pregnancy and her own past antisocial behavior. There was evidence for an association between depression in pregnancy and a juvenile history of CD. Women who were depressed in pregnancy reported significantly more juvenile conduct symptoms than did other women, *M* = 1.3 (*SD* = 1.9) versus *M* = 0.7 (*SD* = 1.3), respectively, which was significant by the Mann–Whitney *U* test, $z = 2.76$, $p < .01$. Women who had been depressed in pregnancy were also somewhat more likely than other women to have been arrested since the age of 18, 4 of 36 depressed women (11%) versus 3 of 81 nondepressed women (4%), but the difference was not significant.

Assortative mating. There was no clear evidence for assortative mating with respect to antisocial behavior. There was no significant association between the mothers' history of arrest and the biological fathers' history of arrest, kappa = .06, *ns*. Furthermore, when the biological father had a history of arrest, women were not more likely to report juvenile conduct symptoms, *M* = 1.0 (*SD* = 1.8) reported by women whose partners had been arrested and *M* = 0.8 (*SD* = 1.4) by women whose partners had not been arrested. Finally, there was no significant association between the mother's depression in pregnancy and the biological father's history of arrest; the father had been arrested in 18 of 38 families (47%) where the mother had been depressed in pregnancy and 28 of 82 families (34%) where she had not been depressed, which was not a significant difference.

Parents' antisocial behavior and adolescents' antisocial outcomes. Associations between parents' antisocial histories and the adolescents' antisocial behavior are presented in Table 4. Only 7 mothers had been arrested in adulthood and their history of arrest in adulthood was unrelated to adolescents' antisocial outcomes. However, the mothers' retrospective reports of antisocial behavior in their own youth did predict their children's antisocial outcomes. The mothers of antisocial adolescents reported $M = 1.4$ conduct symptoms ($SD = 1.9$) in their own teenage years, as opposed to $M = 0.7$ ($SD = 1.3$) reported by the other mothers, $z = -2.48$, $p < .01$ by the Mann–Whitney test. The mothers of adolescents who had shown violent behavior reported $M = 1.9$ conduct symptoms ($SD = 2.3$), as opposed to $M = 0.7$ ($SD = 1.3$) reported by the other mothers, $z = -2.79$, $p < .01$, by the Mann–Whitney test.

Forty-six of 120 biological fathers were known to have been arrested. Of those 46 antisocial men, 16 (34.8%) had offspring who were also antisocial. Of the 74 men who showed no evidence of antisocial behavior, 20 (27%) had biological children who were antisocial, which was not a significant difference.

Effects of depression in pregnancy, controlling for the mother's juvenile conduct symptoms. When the mothers' juvenile conduct symptoms were included in the regression model, neither depression in pregnancy nor the mother's conduct symptoms predicted the general measures of antisocial behavior; both were reduced to nonsignificant trends. However, depression in pregnancy remained a significant predictor of violent outcomes, Wald statistic = 5.71, $p < .02$, OR = 3.72 (95% CI 1.27–10.90), and the mothers' juvenile conduct symptoms independently predicted adolescents' violent behavior, Wald statistic = 4.57, $p < .03$. There was no evidence for an interaction between antenatal depression and maternal conduct symptoms.

When the biological fathers' history of arrest was taken into account, the association between depression in pregnancy and the adolescent's antisocial behavior remained significant, Wald statistic = 4.53, $p < .03$, OR = 2.41 (95% CI 1.07–5.40). Similarly, when the father's history of arrest was controlled for, the mother's depression in pregnancy continued to predict violence, Wald statistic = 7.37, $p < .01$, OR = 4.30 (95% CI 1.50–12.33).

Comparison of Violent and Nonviolent Antisocial Adolescents

The foregoing analyses showed that antenatal depression and the mother's history of conduct problems predicted violent outcomes despite the fact that nonviolent but antisocial youngsters were included in the comparison group for those analyses. Further analyses revealed that, compared to nonviolent antisocial youngsters and the adolescents who were not antisocial, the 18 adolescents who engaged in violent behavior had been exposed to higher levels of adversity in the social environment (Figure 1a). They were more likely to be exposed to maternal depression, particularly in pregnancy (Figure 1b). They also had been exposed to higher levels of a range of maternal risk factors (Figure 1c).

Planned contrasts compared the risk factors experienced by each group of antisocial adolescents (those who were violent, $N = 18$, and those who were not violent, $N = 22$) with the adolescents who were not antisocial. These analyses revealed that the violent youngsters differed significantly from adolescents who were not antisocial with respect to exposure to antenatal depression, $\chi^2(1) = 8.86$, $p < .01$, OR = 4.71 (95% CI 1.61–13.80); the number of time periods when the mother was depressed, $z = -2.87$, $p < .01$ by the Mann–Whitney test; and the number of maternal conduct symptoms, $z = -2.93$, $p < .01$ by the Mann–Whitney test. In contrast, the antisocial youngsters who were not violent did not differ significantly from adolescents who were not antisocial on any of these risk factors.

Sequential Analysis: A Pathway From Conduct Problems in One Generation to Violence in the Next

Because maternal conduct symptoms influenced violent outcomes in particular, in a final analysis, we asked how parental risk factors combined in sequence to predict violent behavior in adolescence. We sought evidence for an intergenerational pathway from the mother's juvenile conduct symptoms to her depression in pregnancy to the child's violent tendencies, and tested whether information about the biological father's antisocial behavior aided prediction of the adolescent's violence (see Figure 2). For the purpose of this final analysis, all variables were dichotomized, with women in the top quartile of conduct symptoms (≥ 1) compared with all others (see Table 6).

We first tested a first-order Markov chain model considering only relations between adjacent variables in this model: *Mother's conduct symptoms → Father's antisocial behavior → Mother's depression during pregnancy → Child's violence at 16 years.* This hypothesized order of events depicts the mother's history of antisocial behavior in her own adolescence, followed by assortative mating with an antisocial man, depression in pregnancy and

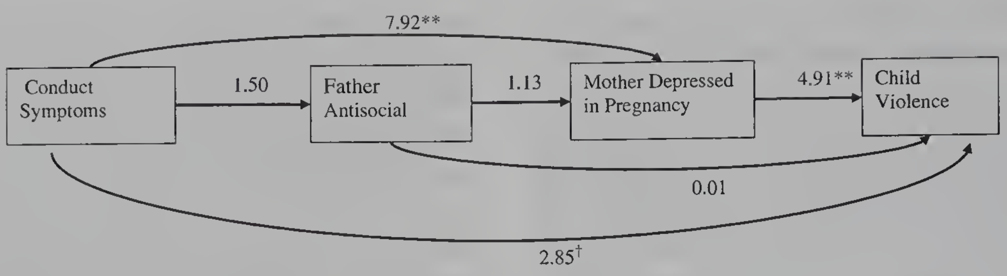

Figure 2. Second-order Markov chain analysis of sequences of risk events: the mother's conduct symptoms, the biological father's history of arrest, the mother's depression during pregnancy, and offspring violence at 16 years of age. In the picture, the numbers above the arrows indicate Wald tests of parameters for the relations between variables. The second-order model had a good fit to data: $\chi^2 = 3.09$, $p = .69$, likelihood ratio $L^2 = 4.14$, $p = .53$, $df = 5$, Bayesian information criterion = −19.79, Akaike information criterion = −5.86.
$^\dagger p < .10$. $^{**}p < .01$.

Table 6

Prediction of Violence at Age 16: Conditional Probabilities for Eight Different Combinations of Risk Events Leading to Violent Outcomes

Mother shows one or more conduct symptoms in adolescence	Biological father has been arrested	Mother becomes depressed during this pregnancy	Child is diagnosed with CD, with aggressive symptoms, and/or has committed violent crimes by 16 years	Conditional probability of violence, given preceding combination of events
Yes	Yes	Yes	Yes	.369
Yes	Yes	No	Yes	.146
Yes	No	Yes	Yes	.355
Yes	No	No	Yes	.138
No	Yes	Yes	Yes	.184
No	Yes	No	Yes	.062
No	No	Yes	Yes	.175
No	No	No	Yes	.058

Note. CD = conduct disorder.

violence in offspring. This first-order model did not have a good fit to the data observed ($\chi^2 = 14.53$, $p = .07$, likelihood ratio $L^2 = 15.29$, $p = .05$, $df = 8$, Bayesian information criterion [BIC] = −23.01, Akaike information criterion [AIC] = −0.71) and was therefore rejected.

We then tested the second-order Markov chain depicted in Figure 2. The results suggest that maternal conduct symptoms predicted depression in pregnancy, but only the mother's depression during pregnancy had a significant relation with the child's violence. Inspection of the conditional probabilities reveals additive effects of maternal conduct symptoms and antenatal depression (see Table 6). When both maternal conduct symptoms and antenatal depression were present, the conditional probability of the child being violent at 16 years, given both maternal risk factors, oscillated between 0.37, if the father had been arrested, and 0.36, if he had not been arrested. On the contrary, if mothers had not reported conduct symptoms, and had not become depressed in pregnancy, the chances of the child being violent at 16 were much lower, being 0.06 whether or not the father was antisocial.

Discussion

The foregoing analyses provide an illustration of ways in which to examine putative early experience effects while testing hypotheses about alternative explanations of those effects. Within a random sample of children born in two relatively disadvantaged urban communities in Britain, we tested for an association between maternal depression in pregnancy and antisocial outcomes in adolescence, and evaluated evidence for alternative hypotheses that might explain the association found. In general, mothers' depression in pregnancy placed their children at a twofold risk for antisocial outcomes, and at a fourfold risk for violent behavior, even when the alternative explanations were taken into account. The influence of depression in pregnancy was not explained by other environmental risk factors at the time of the pregnancy, or by exposure to the mother's illness at later time points, or by the mother's smoking cigarettes and drinking alcohol during the pregnancy. The mother's past history of conduct problems predicted her child's violent behavior but did not remove the effect of depression in pregnancy. Thus, after testing alternative hypotheses, the findings suggest that there was indeed an association between depression in pregnancy and violent antisocial behavior that was not explained by the competing hypotheses that were tested.

This evidence for an association does not, however, specify the causal mechanisms that might be at work. Our findings corroborate other studies linking pregnant women's mental health problems with disruptive behavior disorders and crime in offspring (Maki et al., 2003; O'Connor et al., 2002; Van den Bergh et al., 2006). Indeed, the findings are compatible with the proposition that there will be an increased prevalence of neurobiological deficits in antisocial youngsters, due to the effects of antenatal insults on fetal development (Raine, 2002; Raine et al., 2005; van Goozen et al., 2007). However, longitudinal prediction from antenatal depression to adolescent outcomes does not provide direct evidence for fetal programming. One major limitation of our study is the absence of information about fetal growth and neuroendocrine measures on mother and child.

Furthermore, the pattern of association among risk factors suggested that there might be psychological as well as biological sequelae to the mother's depression in pregnancy. The vast majority of children who were exposed to depression in pregnancy were re-exposed to maternal depression at a later point in their lives; during these subsequent episodes of mental illness, family life and opportunities for socialization may have been compromised. Although re-exposure to maternal depression did not explain the effects of depression in pregnancy, the subsequent episodes may well have conveyed incremental risk. The mother's own experience of depression during pregnancy may have colored her view of the fetus and her subsequent relationship with the child. Our data show that depression in pregnancy is a potent predictor of antisocial outcomes, particularly overtly violent behavior, but do not specify the underlying biological and psychological processes that are involved. It is of course possible that children whose self-regulatory abilities have failed to develop properly, due to early experiences before and after birth, may be particularly vulnerable to the later adversities that result from the mother's lifelong illness and antisocial tendencies.

We had hypothesized that the link between depression in pregnancy and the child's elevated risk for antisocial behavior would be linked to parents' own history of antisocial behavior. Our analyses confirmed that antenatal depression was associated with a history of conduct symptoms, but the mother's conduct symptoms did not explain the effect of antenatal depression. Children were at particular risk for violent behavior when their mothers had both a history of conduct problems and had been depressed in pregnancy. The father's history of arrest did not add predictive power. It would be unwise to conclude that paternal risk factors are unimportant, given that we did not have more detailed information about the father's own history of CD. Nevertheless, the main finding from these analyses was the importance of maternal CD and depressive illness for the development of adolescent antisocial behavior, and violence in particular.

It is possible that the importance of maternal disorder came to the fore in this sample because the sampling frame reduced variation in many of the common sociodemographic predictors of antisocial behavior, which also predict parents' psychopathology. Because the original aim of the study had been to examine perinatal mental illness in a sample where the prevalence of disorder was relatively high, these two urban communities had been chosen for the study (Sharp, 1993). Both the original assessments in the perinatal period and the follow-up assessments confirmed that symptoms of psychopathology and antisocial behavior were relatively common in both parents and offspring. A majority of children in the sample (65%) had been exposed to maternal depression at some point in their lives. In these urban communities, antisocial behavior was also relatively common. Over one third of the children had experienced a parent's arrest. One third of the adolescents themselves had manifested clinically and socially significant instances of antisocial behavior before the age of 16.

The socioeconomic characteristics of the SLCDS population may be seen as a limitation of the study. However, by drawing a random sample from a representative population that was at elevated risk for antisocial outcomes, we controlled for many of the broader environmental risk factors that are associated with antisocial behavior in more heterogeneous samples. Within the South London sample, broad measures of the social environment such as social class, maternal education, maternal IQ, and the family's cultural background did not predict antisocial outcomes. Even when we focused on the relatively small number of adolescents who engaged in overt violence, specific maternal characteristics (age at first birth, marital status, depression, and history of conduct problems), as opposed to the traditional social status measures of class, culture and education, were predictive.

Put another way, the study drew attention to the fact that the upper-middle-class children born in these urban communities were not necessarily protected from adverse outcomes. When compared to the working-class families (nearly 90% of the sample), the middle-class mothers were equally at risk for antenatal depression and their children were equally at risk for antisocial behavior. Our findings draw attention to the fact that not all working-class adolescents living in British cities are at risk for antisocial behavior. A focus on mothers' history of conduct problems and depression during pregnancy, as opposed to broader measures of the social environment, would hold promise for more targeted early interventions to prevent the development of serious antisocial behavior.

Another limitation of the study was its relatively small sample size; the design did not have the statistical power to detect small effects of antenatal influences that have been documented in larger surveys. For example, in this sample, neither smoking nor drinking in pregnancy exerted detectable effects on antisocial outcomes, and did not explain the association with antenatal depression.

It is noteworthy that the children who showed serious levels of violence in adolescence—having committed violent offences or shown violent conduct symptoms in the context of *DSM–IV* CD—were especially likely to have had a nonoptimal family environment. They were more likely than nonviolent children, even those with other antisocial symptoms, to have been exposed to recurring episodes of maternal illness and to have mothers with a history of conduct problems. The fact that antisocial adolescents who were not violent were not significantly different from non-antisocial adolescents in their exposure to most risk factors suggests that there may be a direct link between a child's early adverse experiences and his or her propensity for violence, as opposed to a disposition to show other forms of covert antisocial behavior (see Loeber et al., 1993). This in turn suggests that if there are fetal programming effects linked to the mother's depression in pregnancy, and leading to neurobiological impairment (Raine et al., 2005), they are more likely to influence overt aggression than other forms of rule breaking in childhood and adolescence. In the future, it might be helpful to test fetal programming hypotheses with respect to different categories of symptoms rather than a general diagnosis of CD or a summary measure of externalizing behaviors.

In sum, by testing a series of alternative hypotheses, we have identified two maternal variables that, in combination, led to high rates of antisocial behavior, and violence in particular. The importance of the additive risk of maternal conduct problems and antenatal depression was replicated across two different analytic approaches, logistic regression models and second-order Markov chain analysis. Although the relatively small sample size limited our ability to detect all risk factors that exert small effects on the development of antisocial behavior, the availability of detailed information on an initially random sample of mothers and children studied for 16 years provided a vivid picture of the challenges faced by the children of mothers with a history of conduct problems and lifelong depressive illness.

Appendix: Three Cases Studies That Illustrate Some Individual Pathways to Violent Behavior in Adolescence

Nina: The Daughter of a Mother With Conduct Symptoms but No Depression in Pregnancy

Nina's mother, who was from a working class background, had a juvenile history of truancy and rule breaking. Neither she nor Nina's father had ever been arrested. At age 11, Nina had been oppositional and defiant toward the interviewer and had refused to do part of the interview. In secondary school, she spent little time at school and did not take any of the national GCSE examinations at age 16. By 16 years she had left school. She was arrested for fighting.

Victor: The Son of Antisocial Parents, With Maternal Depression in Pregnancy

Victor was the son of highly educated, upper-middle-class parents who had histories of juvenile conduct symptoms and arrest. Victor's mother, who was diagnosed with depression in pregnancy, had a juvenile history of truancy, breaking rules, arrest, running away, lying, alcohol and drug abuse, stealing, vandalism, and early sex. She had been arrested as a young woman for possession and use of drugs. Victor's father had been arrested for assault as a young man. Victor had a high IQ, had attended a private school, and had done well on the national GCSE examinations at age 16. He was diagnosed with conduct disorder, with aggressive symptoms (bullying, fighting, and use of a weapon), but had never been arrested.

Beatrice: The Daughter of an Antisocial Mother Who Became Depressed in Pregnancy

Beatrice's mother Renee had a juvenile history of truancy, rule breaking, running away, lying, and stealing. She was interviewed in the second trimester of pregnancy and diagnosed as being depressed. She regretted being pregnant and was worried that she would not be a good mother, despite being a mother of two other children. By age 16, Beatrice had been arrested 15 times and tried in court on five occasions on drug charges, for common assault, and for attempted robbery. At the time of the interview, Beatrice was worried about her pending court appearance, when she would either face being electronically tagged or imprisonment. (In the event, she was electronically tagged.) She told the interviewer, ''I don't care about anything, nothing at all. I was being evil, spiteful, getting in a lot of trouble from the police and stuff. I just didn't care.'' Beatrice had also met diagnostic criteria for an anxiety disorder at 11 and depression at 16.

Exploring the Relation Between Prenatal and Neonatal Complications and Later Autistic-Like Features in a Representative Community Sample of Twins

Angelica Ronald, Francesca Happé, Katharina Dworzynski, Patrick Bolton, and Robert Plomin
Birkbeck College, King's College London

Prenatal and neonatal events were reported by parents of 13,690 eighteen-month-old twins enrolled in the Twins Early Development Study, a representative community sample born in England and Wales. At ages 7–8, parents and teachers completed questionnaires on social and nonsocial autistic-like features and parents completed the Childhood Asperger Syndrome Test. Correlations between prenatal and neonatal events and autistic-like features were weak, both in the whole sample (r = .00–.07) and at the 5% quantitative extreme (phenotypic group correlations = .01–.11), after controlling for socioeconomic status and cognitive ability. Neonatal problems showed modest heritability (13%–14%) and significant shared and nonshared environmental influences (55%–59% and 28%–31%, respectively). Differences in identical twins' neonatal problems correlated weakly with their difference scores on autistic-like features (r = .01–.06).

Obstetric factors and pre-, peri-, and neonatal problems have been found to be associated with autism and autistic spectrum disorders (ASD; Bolton et al., 1997; Brimacombe, Ming, & Lamendola, 2007; Burd, Severud, Kerbeshian, & Klug, 1999; Cederlund & Gillberg, 2004; Eaton, Mortensen, Thomsen, & Frydenberg, 2001; Gillberg & Cederlund, 2005; Glasson et al., 2004; Hultman, Sparen, & Cnattingius, 2002; Larsson et al., 2005; Lord, Mulloy, Wendelboe, & Schopler, 1991; Maimburg & Vaeth, 2006; Stein, Weizman, Ring, & Barak, 2006; for a selective review, see Kolevzon, Gross, & Reichenberg, 2007) although a number of studies have found little or no association (Cryan, Byrne, O'Donovan, & O'Callaghan, 1996; Deb, Prasad, Seth, & Eagles, 1997; Levy, Zoltak, & Saelens, 1988; Lord et al., 1991; Mason-Brothers et al., 1990; Piven et al., 1993). These findings of associations between obstetric and neonatal problems and autism alone do not necessarily denote causality and do not speak of the nature of the underlying risk factors. If prenatal and neonatal problems are causal risk factors for autism, it is not clear from existing data if these early complications are an environmental risk factor for autism, are a consequence of environmental insults occurring earlier in gestation, or if they are themselves genetically influenced and may be a result of existing genetic abnormalities in the fetus (Bolton et al., 1997; Gillberg, Gillberg, & Steffenburg, 1990; Goodman, 1990; Hultman & Sparen, 2004).

Twin studies have shown that autism is caused by both genetic influences and nonshared environmental influences (Bailey et al., 1995; Folstein & Rutter, 1977; Steffenburg et al., 1989). Nonshared environmental influences are environmental influences that make children growing up in the same family different and can include epigenetic processes, gene expression, de novo mutations, illnesses, intra- and extrauterine environment, and measurement error (Plomin, DeFries, McClearn, & McGuffin, 2008). In behavior genetics, many "environmental" variables have been shown to be under genetic influence, the so-called nature of nurture (Plomin & Bergeman, 1991). Using a classic twin design, it is possible to partition variance of a variable, such as birth weight or differential parenting,

---

We are indebted to participants of the Twins Early Development Study (TEDS) for making the study possible. The TEDS twin study was supported by a program grant MRC grant G0500079 from the UK Medical Research Council. P.B. was supported by the UK NIHR Biomedical Research Centre for Mental Health at the Institute of Psychiatry, Kings College London and The South London and Maudsley NHS Foundation Trust. A.R. was funded by an Autism Speaks fellowship.

into genetic and environmental components to assess the extent to which it is explained by genetic and environmental influences.

In the original twin study of autism (Folstein & Rutter, 1977), biological hazards associated with the birth process, such as neonatal convulsions, did not explain the concordance rates for autism. However, in 12 of the 17 pairs discordant for autism, it was always the twin who had developed autism that had experienced a biological hazard (using a wide definition of biological hazards that included many features, e.g., multiple congenital abnormalities, delayed breathing after birth, a low birth weight compared to the unaffected cotwin, etc.). A similar pattern of findings was reported in the two later twin studies (Bailey et al., 1995; Steffenburg et al., 1989). In the fraternal or dizygotic (DZ) discordant twin pairs, the fact that the twin with autism showed more biological hazards associated with the birth process could be explained by environmental factors that differed between the twins or by genetic differences, as DZ twins share on average half their DNA (Plomin et al., 2008). However in the monozygotic (MZ) twins who were discordant for autism and for biological hazards at birth, these differences within a twin pair have to be explained by nonshared environmental processes (as defined above) because MZ twins share nearly all of their DNA code. This is why the discordant MZ twin design, which controls for most genetic influences, has proved a valuable tool for investigating whether associations are driven by nonshared environmental processes (e.g., Caspi et al., 2004; Newcombe, Milne, Caspi, Poulton, & Moffitt, 2007; Pike, Reiss, Hetherington, & Plomin, 1996).

As well as studying children with diagnosed autism, it is of interest to explore whether risk factors are present in siblings of children with autism. Several studies have shown that pregnancy and birth complications are associated not only in children with ASD but also in the siblings of children with ASD who show the broader autism phenotype (Bolton et al., 1997; Zwaigenbaum et al., 2002). This suggests that pregnancy and birth complications might be associated with subclinical autistic-like traits as well as with the diagnosed disorder.

A relatively recent approach has been to study dimensional measures of autistic behaviors throughout the range of typical variation and at the quantitative extreme using a general population sample (e.g., Baron-Cohen, Wheelwright, Skinner, Martin, & Clubley, 2001; Constantino et al., 2003; Ronald, Happé, & Plomin, 2005). As well as allowing relation to be explored quantitatively rather than just within categorical clinical groups, which have restricted variance and their own sample biases (Caron & Rutter, 1991), another advantage of studying autistic-like features dimensionally in a general population sample is that it allows the different types of symptoms that make up the autism phenotype—such as social difficulties, communication problems, and nonsocial features such as repetitive behaviors—to be studied separately. Because the autism diagnosis requires children to show clinical-level social, communication, and nonsocial symptoms altogether, these different autistic features are by definition all shown at high levels and in combination with each other in samples of children with autism. A population sample offers the opportunity to study variation in autistic-like traits independently of each other (Happé, Ronald, & Plomin, 2006; Ronald, Happé, Bolton, et al., 2006).

Nevertheless, one study has explored the association between severity of scores on individual Autism Diagnostic Interview–Revised (ADI–R) and Autism Diagnostic Observation Schedule (ADOS) symptom domains and obstetric complications in a sample of children diagnosed with ASD (Wallace, Anderson, & Dubrow, 2008). This study did not find a relation between presence or absence of any obstetric variables and severity on the ADI–R social domain or the ADOS social/communication composite. However the authors did find that hypertension, pre-eclampsia, and generalized edema were all associated with the communication domain, and that hypertension, albuminuria, and generalized edema were associated with the repetitive behaviors domain. Although, as the authors note, it is difficult to measure the full range of severity within a sample of children with diagnosed ASD, and the ADI–R and ADOS are not designed to characterize severity of autistic symptoms, this initial study nevertheless highlights the possibility that obstetric and neonatal problems may show different degrees of association with the different symptoms that characterize autism.

The present study set out to investigate whether parent-rated prenatal and neonatal complications are associated with autistic-like features assessed dimensionally throughout the range of typical variation and at the quantitative extreme, and to explore the association between prenatal and neonatal complications and each type of autistic-like feature (social, communication, and nonsocial) separately, in a community sample. Second, by employing a classical twin design, we explored the extent to which neonatal problems are influenced by genetic and shared and nonshared environmental factors in the general population. Third, by utilizing an MZ differences design, we were able to control for most genetic effects on both neonatal problems and autistic-like features in order to explore whether the association between neonatal factors and autistic-like features in the general population was partly explained by nonshared environmental influences. As prenatal and neonatal problems and autistic-like features could be associated with lower socioeconomic status (SES) and lower cognitive ability in the general population (Newcombe et al., 2007; Hoekstra, Bartels, Verweij, & Boomsma, 2007), these two factors were regressed out of the scales to take account of their possible confounding effect in the analyses.

Method

Participants

The Twins Early Development Study (TEDS) is a UK-based community sample of twins (Oliver & Plomin, 2007; Trouton, Spinath, & Plomin, 2002). The Office for National Statistics (ONS) contacted the families of all live twin births between January 1994 and December 1996 that were recorded and traceable in England and Wales. ONS sent each family a pack including a letter (from ONS), an information leaflet (from TEDS) and a returnable postcard on which parents were asked to give consent for TEDS to contact them. ONS passed on to TEDS the names and addresses of the families that returned the postcard with consent: This was 65.1% of the families that ONS had attempted to contact and this initial sample consisted of 16,810 families in TEDS.

The first contact study was (in all but a few cases) the first point of contact between TEDS and the 16,810 families in the ONS sample. TEDS sent the first contact booklet to all except roughly 500 of the families who either withdrew from TEDS or provided ambiguous responses, had unclear contact details or replied too late for the first contact booklet.

The prenatal and neonatal problems data were collected in this first contact booklet, which was completed by the parent of the twins. The booklets were sent out when the twins were around 1½ years old (*M* = 1.87 years, *SD* = 1.27 years). 13,690 families (81.4% of those contacted) provided valid data at first contact.

Comparing the families that provided data on prenatal and neonatal problems at first contact to the UK population at that time, based on data from the Living in Britain report (ONS, 1997), 92% versus 93% were White, 49% versus 48% of the children were male, and 14% of mothers had one or more A-levels (UK advanced educational qualification) as their highest qualification compared to 9% of women in the United Kingdom.

Families were contacted again when the twins were 7 years old (*M* = 7.06, *SD* = 0.25): of the 14,581 families contacted, 1,679 families were no longer active, but of the active families, 8,163 (63% of active families at age 7; 59% of the families who provided first contact data) provided data at age 7. Parents were also asked for permission to contact the twins' teachers. Of the 7,524 teachers that were contacted, 6,156 (82%) returned data when the twins were age 7 (*M* = 7.20, *SD* = 0.28). The families were contacted approximately 1 year later when the twins were age 8 (*M* = 7.88, *SD* = 0.53); 13,940 families were contacted, 12,317 of whom were active and data were returned from 6,771 families (55% of active families at age 8; 49% of the families who provided first contact data).

The TEDS sample that provided data at ages 7 and 8 was reasonably representative of the UK population. For example, comparing the 7-year TEDS sample to data from the Living in Britain report (ONS, 1997), 94% versus 93% were White, 48% versus 48% were male, and 14% versus 9% of mothers had one or more A-level (UK advanced educational qualification) as their highest qualification. Four percent of children in the TEDS 7-year sample had a statement of special educational needs versus 3% of children in England (Department for Education and Skills, 2002). The same results were found for the sample with 8-year data. Finally, although clinical ASD diagnoses have not yet been completed, the approximate rate of likely ASD cases in this sample of 7,000 families based on the Diagnostic and Wellbeing Assessment (DAWBA) telephone interview instrument (see below) was 154 of 14,000 children (1.10%), which is comparable with the rate of 1.16% reported for all ASDs in a UK epidemiological study (Baird et al., 2006).

In terms of attrition, comparing those families participating at age 7 versus those families who only completed the first contact booklet and did not participate in TEDS subsequent to the first contact, 94% versus 88% were White, 14% versus 14% of mothers had A-levels as their highest educational qualification, and 45% versus 40% of mothers worked. Thus, the samples who provided first contact data and 7- and 8-year data were reasonably representative of the population and of the entire TEDS sample.

In 75% of cases, zygosity was diagnosed using DNA; for others, a parent-rated instrument was used (Price et al., 2000). Exclusions were made for specific medical syndromes such as Down syndrome, Fragile X, and chromosomal anomalies; unavailable zygosity data; no signed consent; missing birth order details; missing first contact data; and extreme perinatal outliers (gestation of < 27 weeks). The final samples after exclusions were 7,402 families with parent data at age 7, 5,982 families with teacher data at age 7, and 5,796 families with parent data at age 8.

Measures

Prenatal and neonatal problems. Parents completed a demographic questionnaire that asked about prenatal issues (12 questions about pregnancy, six about the labor) and neonatal variables (10 questions). The questionnaire included both continuous variables (degree of smoking and alcohol intake during pregnancy, the length of the labor, the length of gestation, the weight and length of the twins, time spent in hospital and in special care, and number of days breastfed) and categorical variables such as whether the mother had amniocentesis during pregnancy (see the Appendix for a full list of items). The questionnaire was based on the prenatal and neonatal reports employed in longitudinal studies at that time, such as the Avon Longitudinal Study of Pregnancy and Childhood and the MacArthur Longitudinal Twin Study, as well as findings from perinatal complications in psychopathology (Parnas et al., 1982) and based on the details that are acquired through Personal Child Health Records from hospitals.

Autistic-like features and potential ASD cases. Parents completed the Childhood Asperger Syndrome Test (CAST; Scott, Baron-Cohen, Bolton, & Brayne, 2002; Williams, Allison, et al., 2006; Williams, Scott, et al., 2005) when the twins were age 8. The CAST is a questionnaire designed to assess autistic-like behaviors for parents to complete in nonclinical settings. The CAST shows good internal consistency in this sample (alpha = .73) and it has been shown that parent reports on the CAST show acceptable test–retest reliability both in a high-scoring sample across a 2-month interval ($r = .67$; Allison et al., 2007) and across a 1-year interval in a community sample ($r = .63$; Ronald, Happé, & Plomin, 2008). Each of the 31 questions is answered in a *yes* (1) or *no* (0) format. The CAST items can be divided into three subscales, based on *DSM–IV* criteria (American Psychiatric Association, 1994; Ronald, Happé, Bolton, et al., 2006).

Parents and teachers also rated the twins' autistic-like features on *DSM–IV*-based social and nonsocial scales (Ronald et al., 2005) when the twins were age 7. The questionnaire was devised to assess social and nonsocial behaviors relevant to autism. The questionnaire was designed to include items that were relevant for assessing the types of social and nonsocial behaviors notable in autism but that also would be seen in the general population. The majority of items were derived from the *DSM–IV* autism criteria (see Ronald et al., 2005). The social scale had 10 items and the nonsocial scale had six items. Each item was rated as *not true* (0), *somewhat true* (1) or *certainly true* (2).

The *DSM–IV*-based social and nonsocial scales showed moderate internal consistency with Cronbach's alphas of .72 and .51 for teacher social and nonsocial scales, and .56 and .53 for parent social and nonsocial scales, respectively. Test–retest data were obtained for these scales from parents of a small independent sample of children aged 9–10, with a 1-week interval. The social scale showed good test–retest reliability ($r = .80$, $N = 35$); the nonsocial scale showed modest test–retest reliability ($r = .50$, $N = 35$). Test–retest data were not available for teacher report. Another index of reliability is the MZ twin correlation because reliability creates an upper limit for MZ twin correlations. MZ twin correlations for both the social and nonsocial scales were moderate to high for both parent (.63–.74) and teacher ratings (.60–.77).

Correlations between teachers and parents were moderate for the social scale ($r = .30$, $p < .001$) and low for the nonsocial scale ($r = .09$; $p < .001$). Similar levels of low to modest agreement have been reported in community samples between teacher and parent ratings of behavior problems (Achenbach, McConaughy, & Howell, 1987), have been observed in samples of children with ASD (Szatmari, Archer, Fisman, & Streiner, 1994) and autistic-like features (Ronald et al., 2008). For this reason the parent and teacher data were analyzed separately.

Because TEDS is a community sample representative of the general population, it is likely to include children with ASDs. Suspected ASD cases have been identified (though not yet clinically assessed) in TEDS via the CAST questionnaire, which acts as a screening tool, or by parents alerting TEDS directly that their child had an ASD, or if parents ticked an ASD box in a questionnaire. Parents of the suspected cases were interviewed by telephone using the DAWBA (Goodman, Ford, Richards, Gatward, & Meltzer, 2000). Potential ASD cases ($N = 154$; 52% Autism, 9% Aspergers, 39% Other Pervasive Developmental Disorder) were identified from these telephone interviews; the twin concordances are reported elsewhere (Bolton et al., 2009). These children were included in the analyses but analyses were also repeated without these DAWBA-ascertained ASD cases.

Other measures. SES was derived from five measures collected in the first contact booklet: highest qualification of mother, highest qualification of father, social class group of father (ranging from unskilled occupation to professional), social class group of mother, and age of mother at the birth of her first child. A single socioeconomic status (SES) composite was created by standardizing these five variables and taking an average score (Asbury, Dunn, & Plomin, 2006). General cognitive ability was assessed at age 7 using Similarities, Vocabulary, and Picture Completion subtests from the Wechsler Intelligence Scale for Children (Wechsler, 1992) and the Conceptual Grouping subtest from the McCarthy Scales of Children's Abilities (McCarthy, 1972; see also Davis & Plomin, 2008).

Analyses. All scales were created by summing items equally and converting to proportions of the total possible score given the number of items completed (which had to be more than half). If there were data for fewer than half the items, the total score was coded as missing.

The categorical items about prenatal and neonatal problems (see the Appendix) were all coded 1 for *yes* and 0 for *no* and were added together into a Prenatal and Neonatal Problems (PNP) scale. This included 17 child-specific and non-child-specific categorical prenatal and neonatal problem items such as "Did you experience high blood pressure during your pregnancy?" (non-child-specific item) and "Did the twin have special care when born (e.g., incubators, etc.)?" (child-specific item). The continuous measures (number of cigarettes smoked during pregnancy, units of alcohol drank during pregnancy, gestation, time in labor, birth length, birth weight, time in hospital, days in special care, days breastfed) were analyzed individually in relation to autistic-like features.

For the twin analyses, a separate Neonatal Problems (NP) scale was created which only included the child-specific categorical variables (see the Appendix) and was created, separately for Twin 1 and Twin 2. High scores on the NP scale indicated a greater number of postnatal child-specific neonatal problems for an individual twin.

Phenotypic analyses. Phenotypic correlations and phenotypic group correlations (Oliver, Dale, & Plomin, 2004) were used to assess the strength of the relation between prenatal and neonatal problems and autistic-like features throughout the general population and at the extreme, respectively. Phenotypic correlations were obtained using STATA 10.0 (StataCorp. 2007). The robust cluster option was used, which corrects standard errors to take account of the nonindependence of data when multiple family members are included (Huber, 1967). Phenotypic group correlations were calculated by dividing the proband's mean standardized score on the unselected variable by the proband's mean standardized score on the selected variable, where probands are defined as all children scoring above a 95% cutoff. Phenotypic group correlations are thus bidirectional: the phenotypic group correlation representing the extreme prenatal and neonatal problems proband group's scores on autistic-like features is different from the phenotypic group correlation representing the extreme autistic-like features group's scores on prenatal and neonatal problem scales. If the regression of one variable on another is linear across the full sample, then the phenotypic group correlation is expected to be similar in magnitude to the correlation for the entire sample (Plomin, Price, Eley, Dale, & Stevenson, 2002) .

Extreme features were defined as scores in the top 95% range of the distribution. This cutoff was chosen as a compromise between the need for a sample size large enough to provide adequate power versus the desire to study extreme scoring groups. General cognitive ability and SES were regressed out of the PNP and NP scales to control for their effects. Similarly, gestation was regressed out of the birth weight variable.

Univariate twin model of neonatal problems. The twin design is based on comparing the within-pair similarity of MZ and DZ twins on a measure or trait of interest (Plomin et al., 2008). The following analyses involved partitioning the variance in neonatal problems in this sample into genetic and environmental influences. Twin analyses can only be carried out on variables that are specific to each child; therefore, neonatal problems, which differ for each child, were studied using a twin model but variables that are shared between twins, such as gestation length, could not be used in the twin model fitting. In accordance with standard quantitative genetics procedure, the neonatal problem scale was corrected for sex prior to analyses. The first step in such analyses was to explore twin similarity coefficients (intraclass correlations; Shrout & Fleiss, 1979). Next, an ACE univariate model was employed, so called because it partitions the total variance into three components: additive genetic (*A*), shared environment (*C*), and nonshared environment (*E*).

Heritability refers to the proportion of variation of a trait in a population explained by genetic influences. *Environmental influences* in the twin design refers to all variance that is not explained by genetic influences (i.e., it has a broader definition than the lay meaning of the environment), and is split into two types, shared and nonshared. Shared environment refers to experiences that make children growing up in the same family similar; nonshared environment refers to environmental influences that make children growing up in the same family different and can include epigenetic processes, gene expression, de novo mutations, illnesses, intra- and extrauterine environment, and measurement error (Plomin et al., 2008).

A univariate twin model partitions variance in a measure or trait into genetic and environmental influences. It does this by observing the degree of covariance shown between twin pairs, separately for MZ and DZ twins. The model assumes that MZ twins share all their genetic influences and all their shared environment, and that DZ twins share on average half their genes and all their shared environment. No measured genes or measured environments are included in the model.

Model fitting was carried out using raw data and the *Mx* program to provide parameter estimates for *A*, *C*, and *E* as well as confidence intervals (Neale, Boker, Xie, & Maes, 2003). The likelihood ratio $\Delta\chi^2$ test (LRT), the Akaike's information criterion, and sample-size-adjusted Bayesian information criterion were used to compare the fit of different models. The LRT uses the log likelihood statistic −2LL with associated *p* values, and selects the most parsimonious model, that is, the model with the best fit given the number of degrees of freedom.

The type of univariate model that was employed here included tests for three types of sex differences and is called a univariate sex limitation model. The model can test, through a series of submodels, whether the same genetic and shared environmental influences affect a trait for males and females (qualitative sex differences), whether genetic and environmental influences have a different degree of magnitude in their influence for males and females (quantitative sex differences), and whether there are variance differences for males and females.

In the univariate sex limitation model the genetic coefficient (r_G) represents genetic relatedness between twins in a pair (Neale & Cardon, 1992). In same-sex MZ groups, r_G is fixed at 1 because MZ twins are assumed to share all their genetic makeup; in same-sex DZ groups, r_G is fixed at .5 because DZ twins share, on average, half their segregating genes. In the DZOS group, r_G is allowed to vary below .5 (the value ascribed to it in DZ same-sex groups) in order to test for qualitative sex differences. The shared environmental coefficient (r_C) is fixed at 1 for MZ and DZ same-sex groups because it is assumed that same-sex twins growing up in the same family share all their shared environmental influences. However, r_C is allowed to vary below this value in the DZOS group. By allowing r_G and r_C to be lower in the DZOS group than in DZSS groups, this tests the extent of genetic and shared environmental overlap between males and females, called qualitative sex differences. Quantitative sex differences can be assessed by allowing *A*, *C*, and *E* parameters to vary for male and female groups. The third sex difference involving variance differences between males and females is assessed by allowing female variance components to be equal to a scalar multiple of the male variance components.

In the full univariate sex limitation model, qualitative and quantitative sex differences are tested. The raw data ACE full model has 15 free parameters: *A* (male), *A* (female), *C* (male), *C* (female), *E* (male), *E* (female), r_G or r_C, male and female variance, and male and female means for MZ, DZ same-sex, and DZ opposite-sex groups. The common effects submodel tests for quantitative sex differences but it sets r_G and r_C at their fixed values (as in the same-sex DZ groups). The scalar submodel tests for sex differences in variance only: it allows the female variance components to be equal to a scalar multiple of the male variance components. Finally, the null submodel fixes all parameters (except for the means) to be equal for males and females.

MZ differences analyses. Difference scores were calculated between MZ twins by subtracting Twin 1's score from Twin 2's score (see Pike et al., 1996). Pearson correlations were then derived for the relation between the difference scores for the prenatal and neonatal variables, and the difference scores for autistic-like features.

Results

A multiple regression of all the prenatal and neonatal problem individual items (listed in the Appendix) as independent variables and autistic-like features as dependent variables using a forced entry method showed that the prenatal and neonatal problem items together explained 5% of the variance in the total CAST score at age 8, and 4%, 4%, and 3% of the variance in the social, communication, and nonsocial subscales at age 8, respectively. At age 7, prenatal and neonatal problems explained 4% of variance in parent-rated social autistic-like features and 2% of variance in parent-rated nonsocial features, and 2% of variance in both the social and nonsocial teacher scales.

Table 1 shows the phenotypic correlations between continuous prenatal and neonatal variables and autistic-like features at ages 7 and 8, which range from ±.00 to ±.10 in magnitude. The PNP scale and the NP scale both showed very low but significant positive correlations with both parent and teacher ratings of both social and nonsocial autistic-like features at age 7 ($r = .03$–$.07$), with the exception of the teacher nonsocial scales that had nonsignificant correlations. Both the PNP scale and the NP scale also showed positive and significant correlations with the parent-rated CAST scales at age 8 ($r = .04$–$.07$), this time with the exception of social autistic-like features, which did not have significant correlations with either PNP or NP scales.

Of the other continuous prenatal and neonatal problem variables in Table 1, length of breastfeeding and number of cigarettes smoked during pregnancy showed the most number of significant associations: Days breastfed correlated negatively with most, though not all, of the autistic-like feature scales. Number of cigarettes during pregnancy correlated positively and significantly with all autistic-like features ($r = .03$–$.10$) except for teacher-rated nonsocial behaviors at age 7. For most of the other continuous prenatal and neonatal variables, correlations were mostly nonsignificant but showed a consistent trend: Gestation correlated for the most part negatively with autistic-like features, birth weight correlated negatively with autistic-like features (with the exception of the CAST social scale), time in hospital correlated positively with autistic-like features (significant for most scales at age 7 but not at age 8), and days in special care correlated positively but weakly with autistic-like features. For alcohol drunk during pregnancy, birth length, and time in labor, correlations varied between positive and negative and were for the most part nonsignificant. Correlations were highly similar after removing the small proportion of children with DAWBA-rated ASDs from the sample.

Table 1

Correlations Between Prenatal and Neonatal Variables and Autistic-Like Features After Correcting for Social Class and General Cognitive Ability

	7 years				8 years

Days breastfed	−.03*	.03	−.04*	.00	−.05**	−.03*	−.03	−.05**

Note. See the Appendix for descriptions of PNP and NP measures. General cognitive ability was assessed in the children at age 7; see the Method section for details of the measure. These correlations take into account relatedness between twin pairs. CAST = Childhood Asperger Syndrome Test; Social = social autistic-like features; Comm = communication autistic-like features; Nonsocial = nonsocial behaviors.

[a] Corrected for gestational age.

*$p < .05$. **$p < .01$.

Table 2 shows the phenotypic group correlations between prenatal and neonatal variables and autistic-like features selected at the quantitative extreme (using a 5% cutoff to define probands), which ranged from ±.00 to ±.11. Overall the strength of the relation between prenatal and neonatal variables and autistic-like features at the extreme was of a magnitude similar to the strength of the relation between prenatal and neonatal variables and autistic-like features throughout the whole sample. For both the PNP scale and the NP scale, there tended to be a stronger relation with autistic-like features at age 8 when selecting the autistic-like feature probands and looking at their PNP or NP scores, than for selecting the children with extreme prenatal and neonatal problems and investigating their scores for autistic-like features.

For the variables in Tables 1 and 2, there were some significant mean sex differences between male and female twins (opposite-sex twins were omitted from these comparisons), with males scoring higher on the PNP scale, $F(1,\ 5225) = 12.34$, $p < .001$, and the NP scale, $F(1,\ 5234) = 26.52$, $p < .001$, and males showing a greater birth length, $F(1,\ 2397) = 6.91$, $p = .01$, and greater birth weight (corrected for gestation), $F(1,\ 5067) = 83.79$, $p < .001$. Time in hospital, days breastfed, days in special care, time in labor, number of cigarettes smoked, and units of alcohol drunk during pregnancy did not differ significantly for males and females. Phenotypic correlations between autistic-like features and the prenatal and neonatal variables did not differ significantly for males and females.

Twin correlations for the NP scale are shown in Table 3. MZ correlations were higher than DZ correlations (although confidence intervals overlapped), suggesting a small amount of genetic influence on the NP scale. MZ correlations were significantly lower than unity, reflecting modest nonshared environmental influences on this scale. DZ correlations were considerably greater than half the MZ correlations, suggesting significant shared environmental influences on this scale. MZ and DZ same-sex correlations differed slightly for males and females, suggesting some small quantitative

Table 3
Twin Correlations for Neonatal Problems Scale

		N
MZM	.72 (.68–.75)	772
DZM	.63 (.59–.67)	735
MZF	.68 (.64–.71)	868
DZF	.60 (.56–.65)	775
DZOS	.53 (.49–.57)	1,445

Note. MZM = monozygotic male; MZF = monozygotic female; DZM = dizygotic male; DZF = dizygotic female; DZOS = opposite-sex DZ twins.

[a] Corrected for gestational age.

sex differences. Finally, the DZOS correlation was significantly lower than the DZ same-sex correlations, implicating that there might be qualitative sex differences on neonatal problems. Twin correlations were highly similar after removing the children with DAWBA-based ASDs from the sample.

The results of the univariate sex limitation model are presented in Table 4. The best fitting model was an ACE full sex limitation model, which meant that both qualitative and quantitative sex differences were significant. As suggested from the twin correlations, the NP scale showed low but significant heritability (13% for males, 14% for females), significant shared environment (59% for males, 55% for females), and modest nonshared environmental influence (28% for males, 31% for females). Parameter estimates could not be equated for males and females. r_G could not be fixed at 0.5 without a significant decrease in fit and was estimated at .00 (.00–.20); r_C was estimated at .85 (.79–.91), demonstrating that there were significant qualitative sex differences on the scale.

Table 5 presents the correlations between MZ pair difference scores for prenatal and neonatal variables with MZ pair difference scores for autistic-like features, which ranged from ±.00 to ±.10. For both the PNP scale and the NP scale, there were weak positive correlations between MZ pair difference scores for prenatal and neonatal problems with MZ pair difference scores for autistic-like features (.01–.06). However, not all these correlations were significant: Of the 7-year scales, only the MZ differences scores in parent-rated social autistic-like features showed significant correlations with the MZ differences scores in the PNP scale (.05) and the NP scale (.05), and of the 8-year scales only the MZ differences scores in the total CAST scale and the communication autistic-like features subscale showed significant correlations with the MZ differences scores in the PNP scale and the NP scale (.05–.06). MZ differences scores in birth weight and time in hospital both showed significant correlations with the MZ differences scores in social but not nonsocial autistic-like features at age 7; similar results were suggested with the 8-year data but the correlations were not significant. MZ differences correlations between days breastfed and autistic-like features as well as between days in special care and autistic-like features were for the most part nonsignificant.

Discussion

This is the first study to explore the relation between autistic-like features, measured dimensionally in the general population and at the quantitative extreme, and parent-reported prenatal and neonatal events. Our hypothesis was that prenatal and neonatal complications, which show an elevated rate in children with ASD, would also show an association with autistic-like features assessed dimensionally in the general population. The analyses also explored whether prenatal and neonatal

complications are more strongly associated with some specific autistic-like features (e.g., social impairments) more than others (e.g., nonsocial autistic-like behaviors). A twin design was employed to explore to what degree an association between prenatal and neonatal events and autistic-like features may be explained by shared genetic influences or by environmental processes.

Strengths and Limitations

We begin with a discussion of the strengths and limitations of the study. First, in terms of limitations, we relied on parent report for our measure of prenatal and neonatal problems collected on average 1½ years after the twins' birth. It has been shown that maternal report shows very good agreement with medical records for information on the child's birth weight, admission to special care baby unit, the method of delivery, maternal smoking during pregnancy, high blood pressure during pregnancy, and breastfeeding, but not for alcohol use during pregnancy and length of labor (Buka, Goldstein, Spartos, & Tsuang, 2004; Githens, Glass, Sloan, & Entman, 1993; Li, Scanlon, & Serdula, 2005; Rice et al., 2007; Sanderson et al., 1998; Seidman, Slater, Ever-Hadani, & Gale, 1987; Tate, Dezateux, Cole, & Davidson, 2005; Tilley et al., 1985; Walton et al., 2000). Maternal characteristics such as educational qualifications have been shown to not influence the level of agreement (Rice et al., 2007). Nevertheless, it would be useful in future research on this issue to obtain hospital records concerning prenatal and neonatal history. Information about placentation was not available in the present study but has proved important in, for example, the study of birth problems in schizophrenia (Davis, Phelps, & Bracha, 1995). Children were not examined for visible dismorphic features that may be associated with prenatal or neonatal history.

Concerning the measurement of autistic-like features, quantitative measures of autistic-like features are still in development—there is no gold standard as there is with ASD diagnoses—and although they may be more appropriate for tapping individual differences in variation than clinical tools, their validity is not as clear-cut. The sensitivity of the CAST as a screening tool for ASD with a designated cut-point of 15 has been shown, in a sample of children clinically assessed using the ADI–R and ADOS, to be 100%, the specificity 97%, but the positive predictive value 50% (Williams et al., 2005). Unfortunately data on the validity the *DSM–IV* scales used at age 7 in our sample, by comparing them to ADOS and ADI–R scores in a clinical sample, are not yet available. Although it has been shown that measures of autistic-like traits are to some extent independent of other forms of psychopathology (e.g., Constantino, Hudziak, & Todd, 2003; Hoekstra et al., 2007), and, as described above, the CAST shows excellent specificity, it is nevertheless possible that parents of children with other disorders endorsed the autistic-like feature items. Therefore, when considering how these findings have relevance to clinical ASD, it is important that they are considered in light of the properties of the measures that were used.

Other considerations include the fact that sampling autistic-like features more proximally in time, such as in early childhood, to the prenatal and neonatal events might have reduced noise and led to higher correlations. This would have made possible a bivariate twin model-fitting analysis to examine directly the degree of shared genetic and environmental effects on neonatal problems and autistic-like features. Possible confounding variables in the intervening years between the pregnancy and birth and the assessment of autistic-like features should be considered, and we did not have information on birth order within the family, so we were not able to take that into account.

Examining a twin sample clearly brings significant advantages; however, it also involves important constraints. Twin analyses can only be carried out on variables that are specific to each child; those that are shared between them, such as gestation length, cannot be used in model fitting. As both twins share most intrauterine environmental exposures, the range of child-specific problems that could be examined using the twin design was narrowed to neonatal experiences in these data. In general, twins also show a much greater incidence of prenatal and neonatal problems than singletons, which means that they are an enriched sample for studying such problems, yet it might also mean that prenatal and neonatal problems in twins do not have as much predictive power as the same level of complications in singletons. Therefore, it is important to give careful consideration to how these findings from a twin sample are generalizable to nontwin samples. The conclusions reached from the twin analyses on neonatal problems might not apply to prenatal or obstetric factors. The twin design assumes that MZ twins are 100% similar genetically, but studies have shown that there are some small differences in DNA in identical twins, for example, differences in copy number variations (Bruder et al., 2008). Finally, like all research designs, the twin design is subject to its assumptions and limitations and it is optimal to try to triangulate on these issues with other research designs such as family and adoption studies (Plomin et al., 2008).

Set against the limitations, the strengths of this study include the fact that data on prenatal and neonatal events were collected in the child's 2nd year, considerably before the data on autistic-like features and therefore can be considered somewhat independent of parents' later concerns about their children's social development (although it is possible that some of these problems may have begun to emerge at the time the prenatal and neonatal data were collected). The longitudinal nature of the study allowed us to test for associations between prenatal and neonatal problems and later autistic-like features that endured across early and middle childhood. Although it remains possible that parent bias explains the relation between parent-rated prenatal and neonatal events and parent-rated autistic-like features, by also including some teacher ratings of autistic-like features we were able to partly circumvent the problem of common methods variance and rater bias. Having two different measures of autistic-like features and two different raters in the present study allowed us to attempt to internally replicate our findings so that they were not specific to a particular measure or rater. However, this strength in the research design left us with some inconsistencies in the results, that is, some significant effects that were not consistent across both measures and raters, and meant that the analyses were subject to multiple testing.

Finally, having a large population sample allowed us to analyze quantitative extreme scoring groups as well as the whole sample. We found that the strength of the association between prenatal and neonatal problems and autistic-like features was consistent across the whole sample and at the quantitative extreme. It should be reiterated that these findings stem from data in a community sample, not a clinical ASD sample. The analyses on "extreme" groups, which were based on a 95% cutoff, will include children who are not as extreme as a diagnosed sample. A second advantage of the large sample was that it provided us with power to detect small effects. Importantly, a review of studies of measured nonshared environmental variables concluded that they tend to account for only small portions of variance in behavior (Turkheimer & Waldron, 2000), which highlights the need for large samples to have power to detect these nonshared environmental effects.

Interpretation of Results

Prenatal and neonatal problems accounted for a small amount (2%–5%) of the variance in autistic-like features. The relation between prenatal and neonatal problems and autistic-like features was weak across the typical range and at the extreme and, when tested using two different measures of autistic-like features and using two different raters, did not provide consistently significant results. Further research is needed to confirm whether the significant results are correct.

Prenatal and neonatal problems did not show a consistently stronger relation with some types of autistic-like features more than others. Correlations did not differ significantly, which may in part be due to their small absolute magnitude. Nevertheless, the data demonstrate the utility of exploring associations with the different types of autistic-like features separately in a general population sample, especially given previous evidence suggesting that different autistic-like features may have different underlying genetic and environmental influences (Happé et al., 2006; Ronald, Happé, Bolton, et al., 2006; Ronald, Happé, Price, Baron-Cohen, & Plomin, 2006).

It is important to note that prenatal and neonatal complications are not exclusively associated with autism and autistic-like features: They have been shown to be associated with intelligence quotient (Newcombe et al., 2007) and many other forms of psychopathology (Eaton et al., 2001). This was reflected in our data in the phenotypic group correlations that, when selecting on children with prenatal and neonatal problems and investigating their autistic-like features scores, showed a much weaker relation than when selecting children with extreme autistic-like features and investigating their prenatal and neonatal experiences. Although we were able to control for the possible confounding effects of cognitive ability and SES in the analyses, it is possible that other correlated medical comorbidities could explain the covariance between autistic-like features and prenatal and neonatal events.

The aim of employing a twin design in this study was to go beyond looking for an association and to explore the extent to which the relation between neonatal problems and autistic-like features might be due to common genetic and environmental influences. The twin model of neonatal problems showed that neonatal problems were explained by low but significant heritability and both shared and nonshared environmental influences. Previous twin studies on these same data have shown that autistic-like features are caused by genetic influences and nonshared environmental influences (Ronald et al., 2005; Ronald, Happé, Bolton, et al., 2006). Previously, there have been suggestions in the autism literature that the association with neonatal problems in autism reflects preexisting genetic abnormality (Bolton et al., 1997; Goodman, 1990). The present study provides data to support this assertion insomuch as we found that genetic influences play a small but significant role in causing variation in neonatal problems in the general population. At a purely speculative level, if there are shared genetic influences between autistic-like features and neonatal problems, this would suggest that some of the genes involved in risk for developing autistic-like features begin to be expressed at the time of birth and affect the developing child in such a way as to increase the risk of problems at birth as well as their later behavior. Such a finding would aid our understanding of the underlying neurobiological pathways involved in the development of autistic-like features. However, in our data neonatal problems were very weakly (and not always significantly) phenotypically associated with autistic-like features and these genetic pathways are only speculative at this stage.

One puzzle about the findings is that twin studies of autism and autistic-like traits suggest, for the most part, that shared environment plays little or no role in their etiology (e.g., Bailey et al., 1995; Folstein & Rutter, 1977; Ronald, Happé, Bolton, et al., 2006; Steffenburg et al., 1989), yet some prenatal factors, such as maternal smoking (which are necessarily shared between both twins in a pair), showed a significant association. One explanation could be that the effect size of these shared environmental risk factors, such as maternal smoking, is small. Another explanation is that prenatal risk factors interact with genetic liability via gene–environment interaction or gene–environment correlation but are not a risk factor on their own.

The key evidence for "nonshared" environmental influences underlying the weak association between neonatal problems and autistic-like features in the general population can be taken from the data on discordant MZ twins. Within this general population sample, differences within MZ pairs in neonatal problems showed a weak (although not consistent) association with differences within MZ pairs in later autistic-like features. The strength of this approach is that these MZ differences correlations are not likely to be caused by shared genetic influences because the comparisons are made within MZ twin pairs, who share most of their DNA. If the results were more consistent, these data would suggest that there are some common nonshared environmental effects causing both neonatal problems and autistic-like features. For example, a nongenetically determined fetal abnormality might predispose a neonate to a more hazardous postnatal course, reflected in both more neonatal problems and later autistic-like features. However, it should be noted that not all of the MZ differences correlations were significant and therefore further evidence is needed for this nonshared environmental association.

Therefore, these analyses explored the possibility that *both* genetic and nonshared environmental influences are involved in causing the association between prenatal and neonatal problems and later autistic-like features, as measured here. A further future step after establishing that both genetic influences and environment may play a role in causing neonatal problems is to investigate the possibility of gene–environment interactions as it is unlikely that these two processes operate in isolation.

In terms of sex differences, mean sex differences were observed in some of the prenatal and neonatal variables, most notably the PNP scale and the NP scale, on which males scored significantly higher than females. This is in line with previous reports showing that males have more birth defects and more adverse neonatal outcomes than females (e.g., Lary & Paulozzi, 2001; Stevenson et al., 2000). Furthermore, the lower female than male MZ correlations for the NP scale suggest the possible involvement of the X chromosome in influencing neonatal problems (Loat, Asbury, Galsworthy, Plomin, & Craig, 2004). Autistic-like features have been shown elsewhere to show significant mean sex differences, with males scoring higher than females (e.g., Baron-Cohen et al., 2001; Ronald, Happé, Bolton, et al., 2006). The univariate twin model of neonatal problems suggested there were some small qualitative and quantitative sex differences in the genetic and environmental causes of neonatal problems. Future research could explore further this link between the sex bias in prenatal and neonatal problems and the sex bias in autistic-like features and ASDs.

In sum, these results provide some support for a weak association between prenatal and neonatal events and later autistic-like features in the general population and at the quantitative extreme. Unfortunately not all associations were found to be significant. Previous reports have shown an association between prenatal and neonatal problems and diagnosed autism. On balance, further research is needed to confirm whether the association also stretches to subthreshold autistic-like features. Neonatal problems showed a small amount of genetic influence in the general population, suggesting that the association between neonatal problems and later autistic-like features could be partly due to shared genetic influences, although this could not be tested directly because of the low correlations. Within-pair differences in identical twins' neonatal experiences correlated weakly with later within-pair differences in autistic-like features, suggesting there may also be common nonshared environmental influences explaining a small amount of the covariance between neonatal problems and later autistic-like features. Again, conclusions are tempered by the inconsistencies in the results. Finally there was not consistent evidence that prenatal and neonatal problems show a stronger association with some autistic-like features more than others. As well as the need for replication, an interesting question for future research will be to explore how the different kinds of prenatal and neonatal experiences that were summed together here, and that are likely to have different etiological components, might contribute individually to risk for autistic-like features.

Appendix

Demographic Questionnaire to Assess Prenatal and Neonatal Variables

Non-child-specific items	Response format
Did you smoke cigarettes whilst pregnant?	Yes/No
How many cigarettes did you smoke each day, on average?	Number of cigarettes
Did you drink alcohol whilst pregnant?	Yes/No
How many units of alcohol did you drink, per week, on average? (1 unit = 1 glass of wine, OR, 1 measure of spirits, OR, ½ a pint of beer)	Number of units
Did you experience any severe stress during your pregnancy (for example, bereavement, serious illness in the family, major money problems)?[a]	Yes/No
During your pregnancy did you experience any of the following	
Amniocentesis[a]	Yes/No/Don't know
High blood pressure[a]	Yes/No/Don't know
Diabetes[a]	Yes/No/Don't know
Toxaemia/pre-eclampsia[a]	Yes/No/Don't know

Appendix Continued

Non-child-specific items	Response format
Vaginal bleeding[a]	Yes/No/Don't know
Rubella/German measles[c]	Yes/No/Don't know
Slow growth of baby/ies[a]	Yes/No/Don't know
Waters breaking more than 11 h before labor[a]	Yes/No/Don't know
How many weeks pregnant were you at the time of delivery?	Number of weeks
Was your labor induced?[a]	Yes/No/Don't know
How long was your labor?	Number of hours
Were there any complications during the birth of your twins?[a]	Yes/No/Don't know
Was the birth by Caesarean section?[a]	Yes expected/Yes emergency/No/Don't know

Child-specific items	
What were the weights of the twins at birth?	
1st born	In lb, oz or kg
2nd born	In lb, oz or kg
What were the lengths of the twins at birth?	
1st born	In cm or in.
2nd born	In cm or in.
Was there any concern about either twin at birth (e.g., did either twin have any breathing problems)?[ab]	
1st born	Yes/No/Don't know
2nd born	Yes/No/Don't know
Did either of the twins have any special care when born (e.g., incubators etc.)?[ab]	
1st born	Yes/No/Don't know
2nd born	Yes/No/Don't know
How long did they stay in special care?	
1st born	Number of days
2nd born	Number of days
How long did the twins stay in hospital after birth?	
1st born	Number of days
2nd born	Number of days
Has either of the twins had to go back to hospital as an outpatient?[ab]	
1st born	Yes/No/Don't know
2nd born	Yes/No/Don't know
Has either of the twins had to go back to hospital to stay overnight? (inpatient treatment)[ab]	
1st born	Yes/No/Don't know
2nd born	Yes/No/Don't know
Have either of your twins	
any medical problems in the first 2 weeks after birth?[ab]	
1st born	Yes/No/Don't know
2nd born	Yes/No/Don't know
physical problems (e.g., cleft lip, hole in the heart)?[ab]	
1st born	Yes/No/Don't know
2nd born	Yes/No/Don't know

Note. "Don't know's" were recoded as missing for all variables.
[a] Item included in Prenatal and Neonatal Problem scale.
[b] Item included in Neonatal Problems scale.
[c] This item was not included in the analyses due to very low frequency of response.

Child Development, January/February 2010, Volume 81, Number 1, Pages 183–199

Frontal Electroencephalogram Asymmetry, Salivary Cortisol, and Internalizing Behavior Problems in Young Adults Who Were Born at Extremely Low Birth Weight

Louis A. Schmidt, Vladimir Miskovic, Michael Boyle, and Saroj Saigal
McMaster University

The authors examined internalizing behavior problems at middle childhood, adolescence, and young adulthood and brain-based measures of stress vulnerability in 154 right-handed, nonimpaired young adults (*M* age = 23 years): 71 (30 males, 41 females) born at extremely low birth weight (ELBW; < 1,000 g) and 83 (35 males, 48 females) controls born at normal birth weight (NBW). Internalizing behavior problems increased from adolescence to young adulthood among ELBW individuals. ELBW adults exhibited greater relative right frontal electroencephalogram activity at rest and more concurrent internalizing behavior problems than NBW controls. Being born at ELBW may have subtle influences on brain–behavior relations even in survivors without major impairments and evidence of these influences may not emerge until young adulthood.

Extremely low birth weight (ELBW) is a phenomenon that provides developmental researchers with a model for understanding how adverse events early in life may impact brain development and developmental outcomes across a variety of domains. Infants born at ELBW (< 1,000 g) are the smallest and most at-risk infants. Because the survival rate of infants born at ELBW has markedly improved over the last few decades due to advances in neonatal care (see Lorenz, 2001, for a review), there is an increased need to track development in ELBW survivors.

Previous research from our group and others has established that children born at ELBW are at risk for a variety of neurodevelopmental and psychiatric disorders and stress-related problems. Saigal, Rosenbaum, Szatmari, and Campbell (1991) reported that the prevalence rate for a number of neurological and neurosensory impairments (e.g., cerebral palsy, hydrocephaly, microcephaly, blindness, and deafness) is significantly higher among children born at ELBW than in normal birth weight (NBW) matched controls. ELBW survivors are also at higher risk for a range of academic, behavioral, social, and psychiatric problems during preschool (Szatmari, Saigal, Rosenbaum, Campbell, & King, 1990; Taylor, Hack, & Klein, 1998), middle childhood (Miller, Bowen, Gibson, Hand, & Ungerer, 2001; Szatmari, Saigal, Rosenbaum, & Campbell, 1993; Taylor, Klein, & Hack, 2000), adolescence (Grunau, Whitfield, & Fay, 2004; Saigal, Hoult, Streiner, Stoskopf, & Rosenbaum, 2000; Saigal, Lambert, Russ, & Hoult, 2002; Saigal, Pinelli, Hoult, Kim, & Boyle, 2003), and young adulthood (Schmidt, Miskovic, Boyle, & Saigal, 2008) compared with their NBW counterparts.

A similar pattern of stress-related difficulties such as psychiatric, behavioral, and socioemotional problems noted in children, adolescents, and young adults born at ELBW has been documented in children, adolescents, and young adults who were born at very low birth weight (VLBW < 1,500 g; see Chapieski & Evankovich, 1997; Hack, Klein, & Taylor, 1995; Schothorst & van Engeland, 1996; Zwicker & Harris, 2008, for reviews). These

behaviors include: lower levels of social competence (Ross, Lipper, & Auld, 1990), more psychiatric and behavioral problems (Botting, Powls, Cooke, & Marlow, 1997; Cooke, 2004; Dahl et al., 2006; Hack, Cartar, Schluchter, Klein, & Forrest, 2007; Hack et al., 2002; Hack et al., 2004; Hack et al., 2005; Indredavik, Vik, Heyerdahl, Kulseng, & Brubakk, 2005; Levy-Schiff et al., 1994; Reijneveld et al., 2006; Richards, Kelly, Doyle, & Callanan, 2001; Sykes et al., 1997), and lower self-concept (Richards et al., 2001) in children, adolescents, and young adults born at VLBW. Hack et al. (2007) also found that, although VLBW participants reported similar health, well-being, and functioning compared with NBW controls, they exhibited greater risk avoidance. Hack et al. suggested that reduced resilience in VLBW individuals may prove detrimental to their future adult health. In other high-risk birth groups, Allin et al. (2006) recently reported significantly lower extraversion and higher neuroticism scores in adults born very preterm (< 33 weeks gestation age) compared with full-term control adults.

Although pre- and perinatal risk factors such as low birth weight and prematurity are presumed to shape the developing brain and predict the development of stress-related problems (Als, 1995), we know little about their impact on brain-based and behavioral measures of stress vulnerability in adult survivors. The reason for this lack of attention is largely that there have been relatively few opportunities to study ELBW survivors as young adults. Because medical advances have improved survival rates further for infants born at ELBW only in the last few decades (Lorenz, 2001), the long-term impact of pre- and perinatal risk factors on stress vulnerability can now be examined in adult survivors.

Frontal Electroencephalogram (EEG) Asymmetry and Stress Vulnerability

One approach to the study of stress vulnerability has been to use measures of EEG activity to examine patterns of regional brain asymmetry in infants, children, adults, and clinical populations (Davidson, 1993, 2000; Fox, 1991, 1994). Davidson (1993, 2000) and Fox (1991, 1994) have argued that emotions are organized around approach-withdrawal motivational tendencies. The experience of positive emotions (e.g., joy, happiness, interest) facilitates approach-related responses whereas the experience of negative emotions (e.g., fear, sadness, disgust) facilitates withdrawal-related responses. Moreover, the anterior cerebral hemispheres are differentially lateralized for approach–withdrawal responses and the regulation of emotion. The left frontal region subserves approach-related behaviors and emotions, whereas the right frontal region subserves withdrawal-related emotions.

Over the past three decades, researchers have used the frontal EEG asymmetry-emotion model as a theoretical platform to derive predictions about emotional regulation and socioemotional development (see Coan & Allen, 2004, for a review). Overall, studies have shown that the pattern of resting frontal EEG alpha asymmetry (a) reflects a bias to experience either positive or negative emotion, (b) is related to individual differences in affective style, and (c) predicts psychopathology across development. Individuals who exhibit greater relative left frontal EEG activity at rest are social, extraverted, and outgoing, whereas those who exhibit greater relative right frontal EEG activity at rest are shy, anxious, and depressed.

For example, infants who are fearful and easily distressed (Buss et al., 2003; Fox, Bell, & Jones, 1992), toddlers who are behaviorally inhibited (Calkins, Fox, & Marshall, 1996; Fox, Bell, & Calkins, 1994), and children who are socially withdrawn (Fox, Henderson, Rubin, Calkins, & Schmidt, 2001; Fox et al., 1995), shy (Theall-Honey & Schmidt, 2006) and score high on internalizing behaviors (Fox, Schmidt, Calkins, Rubin, & Coplan, 1996) all exhibit greater relative right frontal EEG activity at rest. Adults who are shy (Schmidt, 1999) and socially anxious (Beaton et al., 2008) are known to display greater relative right frontal EEG activity at rest. In addition, clinically depressed adults are characterized by greater relative right frontal EEG activity at rest even when their symptoms of depression are in remission (Henriques & Davidson, 1990). Individuals who exhibit stable resting right, versus left, frontal EEG activity across time are also known to score high on measures of internalizing behaviors such as behavioral inhibition and withdrawal (Sutton & Davidson, 1997).

Studies have noted short- and long-term stability over time and context in resting frontal EEG alpha asymmetry and power measures in healthy individuals as well as some clinical populations. Schmidt and his colleagues reported stability in frontal EEG asymmetry measured second-by-second in healthy infants (Schmidt, 2008) and across different stages of sleep in adults (Schmidt, Cote, Santesso, & Milner, 2003). Tomarken, Davidson, Wheeler, and Kinney (1992) found stability in frontal EEG asymmetry and power across 3 weeks in healthy adults. Still other studies have noted stability across a longer period of time (i.e., 8- and 16-week intervals) in frontal alpha asymmetry in nonmedicated clinically depressed individuals, where changes in asymmetry were not related to changes in clinical state (Allen, Urry, Hitt, & Coan, 2004). More recent studies by Fox's group have reported long-term stability in the resting frontal asymmetry metric over a 6-month to 3-year interval in preschool- (3–5 years) and school-aged (6–9 years) children (Vuga, Fox, Cohn, Kovacs, & George, 2008), and over a 1- to 3-year interval in healthy adults and in adults with a history of major depression (Vuga et al., 2006). More recently, Schmidt and colleagues have noted long-term stability in the pattern of frontal EEG alpha asymmetry over a 3-year period in a sample of stable community outpatients with schizophrenia before and after controlling for positive and negative symptoms of the disorder (Jetha, Schmidt, & Goldberg, 2009) and over a 6-month period in adolescent females exposed to child maltreatment (Milkovic, Schmidt, Georgiades, Boyle, & MacMillen, 2009). Because the pattern of frontal EEG asymmetry at rest is stable across time (Tomarken et al., 1992) and context (Schmidt et al., 2003), and its appearance early in life is predictive of socioemotional and stress-related problems (see Coan & Allen, 2004; Fox et al., 1995; Fox et al., 1996; Fox et al., 2001), some have argued that this metric indexes stress vulnerability (Coan & Allen, 2004; Davidson, 1993, 2000; Fox, 1991, 1994).

There have been, however, no studies that have examined the impact of pre- and perinatal risk factors on resting frontal EEG asymmetry measures in adult survivors. The EEG studies that do exist are concerned primarily with premature infants at birth in neonatal intensive care units (Victor, Appleton, Beirne, Marson, & Weindling, 2005) or those early in the postnatal period (Beckwith & Parmelee, 1986; Duffy, Als, & McNulty, 1990; Hayakawa et al., 2001; Vecchierini, Andre, & d'Allest, 2007) in relation to behavioral and cognitive outcomes. Some researchers also have examined the EEGs of premature infants in relation to later manifestations of congenital brain disorders (Ellingson, Dutch, & McIntire, 1974). A primary goal of the present study was to examine the patterns of resting frontal EEG alpha asymmetry in young adults born at ELBW.

Salivary Cortisol and Stress Vulnerability

A second approach to the study of stress vulnerability has been to use neuroendocrine measures such as salivary cortisol (see Gunnar, 2000; Gunnar & Tagle, 2008, for reviews). The endocrine system has long been implicated in the regulation of emotion (see Gunnar, 1994). Cortisol is one of the critical molecules of the endocrine system. It is produced in response to stress and is easily measured in saliva. A number of studies have shown that cortisol increases in response to stress and the experience of fear in human infants, children, and adults, and baseline salivary cortisol predicts individual differences in stress vulnerability (see Gunnar & Tagle, 2008, for a review).

Human infants with high basal cortisol levels exhibit more freezing behavior in response to novel stimuli and greater relative right frontal EEG activity (Buss et al., 2003). Infants who remained temperamentally distressed from 9 to 13 months of age exhibited increases in adrenocortical activity during the presentation of laboratory vignettes (Gunnar, Mangelsdorf, Larson, & Hertsgaard, 1989). Kagan, Reznick, and Snidman (1987, 1988) reported that temperamentally shy and behaviorally inhibited children exhibited higher morning basal cortisol levels compared with uninhibited children. Schmidt and his colleagues replicated the morning basal cortisol finding in temperamentally shy preschoolers (Schmidt et al., 1997). In addition, adults with agitated depression (i.e., depression with comorbid anxiety) are also known to be characterized by high basal cortisol levels (Gold, Drevets, & Charney, 2002; Gold, Goodwin, & Chrousos, 1988a, 1988b).

Gunnar and her colleagues found that stressful events early in life shaped neuroendocrine responses. Gunnar's group noted high cortisol levels among 6- to 12-year-old children who spent more than 8 months in Romanian orphanages in their first years of postnatal life compared with early adopted children and nonadopted North American children (Gunnar, Morison, Chisholm, & Schuder, 2001). Gunnar and her colleagues also reported that behaviorally inhibited children who were in insecure attachment relationships displayed greater increases in salivary cortisol during fear-eliciting conditions compared with uninhibited and securely attached children (Nachmias, Gunnar, Mangelsdorf, Parritz, & Buss, 1996).

There have been relatively few studies that have examined the impact of pre- and perinatal risk factors on adult salivary cortisol levels (although see Kajantie & Raikkonen, in press, for a recent review). One exception is the work of Wust, Entringer, Federenko, Schlotz, and Hellhammer (2005) who recently reported that birth weight was associated with salivary cortisol responses to psychosocial stress in adult life. Lower birth weight due to twin births predicted higher cortisol reactivity in young adulthood. A second goal of the present study was to examine patterns of resting baseline salivary cortisol levels in young adults born at ELBW.

The Present Study

We examined whether being born at ELBW would have any long-term negative impact on brain–behavior relations and stress vulnerability. More specifically, we were interested in testing whether ELBW survivors without major impairments would exhibit more internalizing behavior problems in middle childhood, adolescence, and young adulthood and more stress vulnerability as indexed by two brain-based measures than their NBW peers. To our knowledge, there appear to be no studies examining multiple brain-based and behavioral measures of stress vulnerability in young adult survivors who were born at ELBW. It is possible that there may be subtle influences on brain development due to pre- and perinatal risk factors that may only manifest later in life (see, e.g., Miskovich, Schmidt, Boyle, & Seigel, 2008). For example, a recent study reported reduced fertility in adult survivors of extreme prematurity (Swamy, Østbye, & Skjaerven, 2008). Although causality could not be inferred from this study, the results do raise the possibility that pre- and perinatal risk factors may negatively impact development across different domains in subtle ways that do not manifest (or are not observed) until young adulthood.

By design, we selected relatively homogenous groups from the ELBW and NBW cohorts composed of participants who were free from neurosensory or psychiatric impairment, right-handed, and tested at approximately the same time of day, as these variables are known to influence the study measures. The two groups did not differ significantly on key maternal and familial risk factors such as parental social class, education, family functioning, maternal psychopathology, and social support measures collected in middle childhood, adolescence, and young adulthood. The two groups also did not differ on any demographic, individual, or familial risk factors other than birth weight from infancy.

We collected regional resting brain EEG activity, baseline salivary cortisol, and measures of internalizing behavior problems in ELBW young adults and NBW controls. These measures were examined in relation to measures of child, adolescent, and young adult internalizing behavior problems. The ELBW cohort has been followed longitudinally from birth and assessed at key developmental milestones (see Saigal, Szatmari, Rosenbaum, Campbell, & King, 1990; Saigal et al., 1991, 1996, 2003; Saigal, Stoskopf, Streiner, Boyle, et al., 2006 Szatmari et al., 1990; Szatmari et al., 1993).

Hypotheses

We made the following predictions: (a) young adults born at ELBW would exhibit significantly more internalizing behavior problems, greater relative right frontal EEG activity at rest, and higher baseline salivary cortisol levels compared with their NBW controls; (b) internalizing behavior problems would increase from adolescence to young adulthood in ELBW adults; and (c) greater relative right frontal EEG activity would be related to concurrent internalizing behavior problems and higher salivary cortisol levels.

Method

Participants and Study Overview

Extremely low birth weight. The ELBW cohort comprised 397 predominantly Caucasian infants (birth weight = 501–1,000 g) born between 1977 and 1982 to residents of a geographically defined region in central-west Ontario, Canada, and recruited at birth. Of these 397 infants, 179 (45%) survived to hospital discharge from the neonatal intensive care unit. There were 13 late deaths; therefore, 166 survived to young adulthood. Adults who were born at ELBW were followed longitudinally from birth, and neurosensory impairments (e.g., cerebral palsy, blindness, deafness, mental retardation, microcephaly) were diagnosed by a neonatologist and a developmental pediatrician. By design, we chose to constitute a fairly homogeneous group of participants and therefore excluded individuals with neurosensory impairments ($n = 46$), psychiatric problems ($n = 2$), and those who were non-right-handed (cf. Oldfield, 1971; $n = 25$). We selected only right-handed individuals because left-handers are known to differ in the lateralization of emotion (Heller & Levy, 1981). Of the 93 ELBW adult survivors eligible to participate, 7 were lost to follow-up, 4 refused the entire young adulthood study, and 11 either refused or were unable to be recalled to the laboratory. A total of 71 (76%) eligible ELBW adult survivors participated in this study.

Normal birth weight. The NBW control group comprised 145 individuals who were selected from a random sample of children born at term and obtained from class lists of 8-year-old children from several local public school boards, and were of similar race, sex, and socioeconomic status distribution as the ELBW cohort (Szatmari et al., 1993). The controls were not followed prospectively from birth. Of the 145 NBW controls originally enrolled, we excluded those with neurosensory impairments (*n* = 3), non-right-handed individuals (*n* = 27), and those who had epilepsy and multiple sclerosis at young adulthood (*n* = 2). Of the 113 eligible NBW control participants, 4 were lost to follow-up, 7 refused the entire young adulthood study, and 19 either refused or were unable to be recalled to the laboratory. A total of 83 (74%) NBW adults participated in the present study (see Table 1 for an overview).

The 154 (ELBW, *n* = 71; NBW, *n* = 83) participants in this study were part of a larger study examining transition to young adulthood (Saigal, Stoskopf, Pinelli, et al., 2006; Saigal, Stoskopf, Streiner, Boyle, et al., 2006), health status (Saigal et al., 2007), and quality of life (Saigal, Stoskopf, Streiner, Paneth, et al., 2006) of individuals born at ELBW. The analyses next focus on the measures of internalizing behavior problems, resting regional EEG activity and salivary cortisol collected during their young adulthood visit to our laboratory as well as measures of internalizing behavior problems collected during their middle childhood and adolescent follow-up visits.

Instruments and Measures

Internalizing behavior problems measured at middle childhood. Both cohorts of participants and their parents (ELBW: *n* = 64; NBW: *n* = 80) were asked to complete the Ontario Child Health Study (OCHS; see Boyle et al., 1987) at the middle childhood visit (see Szatmari et al., 1993). The OCHS scales are composed of a psychiatric checklist that measures conduct disorder, oppositional defiant disorder (ODD), attention deficit hyperactivity disorder (ADHD), overanxious disorder, separation anxiety, and depression based on criteria of the *Diagnostic and Statistical Manual of Mental Disorders, Third Edition, Revised* (*DSM–III–R*; American Psychiatric Association, 1987). The externalizing problems scale is formed by summing the first three scales and the internalizing problems by summing the last three scales. The Child Behavior Checklist (CBCL; Achenbach & Edelbrock, 1983) and the original OCHS scale (Boyle et al., 1987; Offord et al., 1987) provided the basic pools of items and additional items were added by consensus when necessary, to describe a particular disorder. Each item has three response categories *never or not true, somewhat or sometimes true*, or *very or often true*, with scores of 0, 1, or 2, respectively. Respondents were asked to base their answer on the preceding 6 months. Of particular interest to the present study was in the internalizing behavior problems scale (i.e., overanxious disorder, separation anxiety, and depression). All three subscales were interrelated within age (*ps* < .05). Accordingly, the three individual subscales were first *z*-scored and then summed to form a separate composite measure of *middle childhood internalizing behavior problems*. The composite measure of middle childhood internalizing behavior problems was then *z*-scored.

Internalizing behavior problems measured at adolescence. The participants in both cohorts (ELBW: *n* = 65; NBW: *n* = 74) were asked to complete the Ontario Child Health Study–Revised (OCHS–R; see Boyle et al., 1993) scales, which were self-administered at the adolescent visit (see Saigal et al., 2003). Of particular interest from the OCHS–R was the internalizing behavior problems scale (i.e., overanxious disorder + separation anxiety + depression). All three subscales were interrelated within age (*ps* < .05). Accordingly, the three individual subscales were first *z*-scored and then summed to form a separate composite measure of *adolescent internalizing behavior problems*. The composite measure of middle childhood internalizing behavior problems was then *z*-scored.

Internalizing behavior problems measured at young adulthood. At the young adult visit, the participants in both cohorts (ELBW: *n* = 71; NBW: *n* = 82) completed (a) the CBCL Youth Self-Report (YSR; Achenbach, 1991) measure of particular interest from the YSR was the internalizing behavior problems scale (social withdrawal + somatic complaints + anxiety/depression scales); (b) the Spielberg Trait Anxiety Inventory (Spielberger, Gorsuch, Lushene, Vagg, & Jacobs, 1983), which is a 20-item Likert-format measure that indexes trait anxiety (e.g., "I am a steady person," "I lack self-confidence"); and (c) items related to social phobia from the interviewer administered World Organization Composite International Diagnostic Interview Short-Form (CIDI–SF; Kessler, Andrews, Mroczek, Ustun, & Wittchen, 1998). Sample items include: Have you ever had such a strong, unreasonable fear of: (a) giving a speech or speaking in public, (b) eating or drinking where someone could watch you, (c) talking to people because you might have nothing to say or might sound foolish, (d) writing while someone watches, (e) taking part or speaking in a meeting or class, (f) going to a party or other social outing? Response format is *yes* or *no*. The CBCL YSR Internalizing Scale, Spielberger Trait Anxiety, and CIDI–SF Social Phobia scale were all highly interrelated (*ps* < .05). Accordingly, each was first *z*-scored and then added together to form a composite measure of *young adulthood internalizing behavior problems*. This composite measure was then *z*-scored.

Demographic risk. Information on demographic factors was obtained from the parents through parent report questionnaires at the middle childhood (see Szatmari et al., 1993), adolescent (see Saigal et al., 2003), and young adult visits. Parental socioeconomic status was measured using the Hollingshead index of social position (Hollingshead, 1969). Maternal education was assessed by responses to the OCHS questionnaire (Boyle et al., 1987).

Maternal and familial risk. Information on family factors was obtained from parent report questionnaires at the middle childhood (see Szatmari et al., 1993), adolescent (see Saigal et al., 2003), and young adulthood visits. Maternal mood was measured by a 10-item scale derived from the Bradburn Scale of Positive and Negative affect (Bradburn, 1969). This scale is composed of 5 items that measure positive affect and 5 items that measure negative affect. Maternal depression was indexed using the Center for Epidemiologic Studies–Depression Scale (CES–D; Carpenter et al., 1998; Radloff, 1977). Maternal anxiety was measured by the Speilberger State–Trait Anxiety Inventory (Spielberger et al., 1983). Maternal social support was assessed using Social Support Index (SSI; McCubbin, Patterson, & Glynn, 1987). The SSI measures degree of social networks and connectedness. Family functioning was measured by the 12-item general functioning scale derived from the McMaster Family Assessment Device (Byles, Byrne, Boyle, & Offord, 1988). This instrument assesses family functioning on six dimensions: problem solving, communication, roles, affective responsiveness, affective involvement, and behavior control.

Individual risk. Young adults from both cohorts completed the SSI (McCubbin et al., 1987), the CES–D (Carpenter et al., 1998; Radloff, 1977), and the Rosenberg Self-Esteem Short Form (Rosenberg, 1965). Body mass index was measured by dividing participant weight by height, squared. Level of respiratory support (0 = *none* to 4 = *high*) at birth also was examined within the ELBW group.

Procedures

Upon arrival to the laboratory at the young adult visit, we explained the procedures to the participants and obtained written informed consent. After allowing the participants 30 min to adjust to the laboratory, three saliva samples were collected approximately 15 min apart. Then the participant was led to a room used for EEG testing. Regional EEG was recorded during a 2-min resting baseline (1 min eyes open [EO], 1 min eyes closed [EC]) condition. Studies have shown that EEG power estimates as short as 2 min have proven reliable (Allen et al., 2004; Schmidt, 2008).

After the EEG recording, the EEG cap was removed, and the participant was debriefed and provided with remuneration for participating. All procedures were conducted under the supervision of trained research staff and approved by the McMaster University Health Sciences Research Ethics Board. The study was conducted from 2001 to 2004.

EEG Procedures and Measures

EEG recording. Regional EEG was collected using a Lycra stretch cap. The cap electrodes are positioned according to the 10/20 system of the International Federation (Jasper, 1958). The experimenter used the blunt end of a Q-tip in combination with an abrasive gel (Omni-prep, D.O. Weaver & Co., Aurora, CO) and gently abraded each electrode surface. Each electrode site was then filled with a small amount of electrolyte gel that served as a conductor. Electrode impedances below 10 K ohms per site and within 500 ohms between homologous sites were considered acceptable.

EEG was recorded from the left and right anterior and posterior regions of the scalp (i.e., midfrontal: F3, F4; central: C3, C4). EEG activity was collected in posterior regions to examine if asymmetry differences were specific to the frontal region. All active EEG sites were referenced to Cz during acquisition.

A calibration signal (10 Hz/0.47 V rms sine wave) was input through each amplifier prior to each data collection. The output of this signal was 50 μV, with a gain of 10,000. The five channels were amplified by individual SA Instrumentation Bioamplifiers, with filter settings for all channels set at 1 Hz (high pass) and 100 Hz (low pass). The data from all five channels were digitized online at a sampling rate of 512 Hz.

EEG data reduction and quantification. The EEG data were visually scanned for artifact due to movement (e.g., eye blinks, body movements) and edited out using software developed by James Long Company (EEG Analysis Program, Caroga Lake, NY). If artifact was present in one channel, then data in all channels were excluded. All artifact-free EEG data were analyzed using a discrete Fourier transform, with a Hanning window of one sec width and 50% overlap. Regional EEG power (in μV^2) was derived in the alpha (8 to 13 Hz) frequency band separately for the EO and EC conditions. It is well documented that this EEG frequency band is linked to individual differences in stress vulnerability (see Coan & Allen, 2004; Davidson, 2000). Because EEG power in the EO and EC conditions was highly related for each of the sites ($rs > .80$, $ps < .01$), a composite measure of resting EEG alpha power was computed separately for each EEG site by averaging power in the EO and EC conditions. This aggregate measure is known to produce a more reliable estimate of EEG power and asymmetry than separate EO and EC conditions (see Tomarken et al., 1992). A separate EEG asymmetry measure was then computed for each region (e.g., F4 alpha power *minus* F3 alpha power). Because EEG power is inversely related to activity, negative values on the frontal asymmetry metric reflect greater relative right EEG activity (Davidson & Tomarken, 1989). The two study groups did not differ in the amount of EEG artifact data removed or in the amount of artifact-free EEG data used in the analyses.

Salivary Cortisol Procedures and Measures

Data collection. Each participant was asked to refrain from eating or drinking 1 hr prior to coming to the laboratory and to report any atypical recent life events, as these factors are known to influence cortisol levels. Each participant was asked to donate three individual saliva samples during the laboratory visit. Passive saliva was collected by having each participant expectorate into a 50-μl cryogenic tube. Approximately 50 μl of saliva were collected at each sample. The average time of day for saliva collection was approximately 1,300 hr. The time of day that the three saliva samples were collected did not vary between groups or systematically with any of the other study measures.

Salivary cortisol assay determinations. All saliva samples were transported on ice and stored at −20°C prior to assays. Saliva was centrifuged at 3,000 × *g* for 15 min, and only the supernatant was assayed in the Neuroendocriniology Laboratory at Brock University (St. Catharines, ON, Canada). All enzyme immunoassays were carried out on NUNC Maxisorb plates. Cortisol antibodies (R4866) and corresponding horseradish peroxidase conjugate were obtained from C. Munro of the Clinical Endocrinology Laboratory, University of California, Davis. Steroid standards were obtained from Steraloids, Inc. (Newport, RI). Each sample was assayed in duplicate and averages were used. Interplate variation (CV) was 6.45%, whereas intraplate variation was 6.51%. Because all three salivary cortisol samples were correlated ($ps < .05$), they were aggregated and an average measure of baseline salivary cortisol (expressed in ng/ml) was computed. The natural log (ln) of this composite measure was then computed to reduce skewness.

Missing Data

Of the 154 participants, EEG data were missing from 21 participants (6 ELBW, 15 NBW), owing to several reasons: 6 (3 ELBW, 3 NBW) refused the EEG procedure, 10 (2 ELBW, 8 NBW) were excluded either due to equipment failure ($n = 4$) or excessive movement and motor artifacts rendered their EEG unusable ($n = 6$), and 5 (2 ELBW, 3 NBW) were excluded because they had extreme EEG power values +3 *SD* above the mean. The

ELBW and NBW groups did not differ, nor did males and females disproportionately differ in the number of participants excluded or without usable data.

Results

Preliminary Analyses

Sociodemographic risk factors. Sociodemographic data for the ELBW and NBW young adult groups are provided in Table 2. Separate chi-square analyses revealed that there were no significant differences in group membership for gender, parental social class, and educational status (*ps* $> .05$). A between-groups t test also revealed that the two groups did not differ on age at assessment at the young adult visit ($p > .05$). In addition, there were no significant between-group differences on any of these sociodemographic factors at their middle childhood (see Szatmari et al., 1993) and adolescent (see Saigal et al., 2003) visits.

SD	1.4	1.1	

[a] Based on Hollingshead (1969) classification. Data were missing for 3 ELBW participants and 2 NBW participants. [b] Data were missing for 1 NBW participant.

Individual, maternal, and familial risk factors. A separate analysis of variance (ANOVA) with group (ELBW, NBW) as the between-groups factor was performed on the separate individual, maternal, and familial risk factors. These analyses revealed that the two groups did not significantly differ on individual social support, depression, self-esteem, and body mass index, or on maternal social support, mood, depression, anxiety, social support, and family functioning measured at the young adult visit (*ps* $> .05$). In addition, the two groups did not differ on these individual, maternal, and familial risk factors at their middle childhood (see Szatmari et al., 1993) or adolescent (see Saigal et al., 2003) visits.

Between-Group Analyses

Internalizing behavior problems at middle childhood, adolescence, and young adulthood. We predicted that individuals born at ELBW would exhibit significantly more internalizing behavior problems than those born at NBW. To test this prediction, we performed a repeated measures analysis of variance (ANOVA) with group (ELBW, NBW) and sex (male, female) as the between-groups factors, and age (middle childhood, adolescence, young adulthood) as a within-groups factor. The dependent measure was the composite z-score measure of internalizing behavior problems.

The analyses revealed a significant main effect for sex, $F(1, 129) = 4.81$, $p < .05$. Overall, females ($M = 0.114$, $SE = 0.08$) exhibited significantly more internalizing behavior problems than males ($M = -0.153$, $SE = 0.09$). The analyses also revealed a significant Group × Age interaction, $F(2, 128) = 4.74$, $p < .01$ (see Figure 1).

To decompose this interaction, we performed a separate ANOVA at each age, with group (ELBW, NBW) as the between-groups factor. The dependent measure was the composite z-score measure of internalizing behavior problems at each age. As predicted, the analyses revealed a significant main effect for group on internalizing behavior problems only at young adulthood, $F(1, 131) = 4.97$, $p < .05$, Cohen's $d = 0.35$ (see Figure 1). ELBW adults ($M = 0.21$, $SE = 0.14$) exhibited significantly more internalizing behavior problems as young adults than their NWB peers ($M = -0.19$, $SE = 0.11$). Pairwise t tests also revealed that, as predicted, ELBW

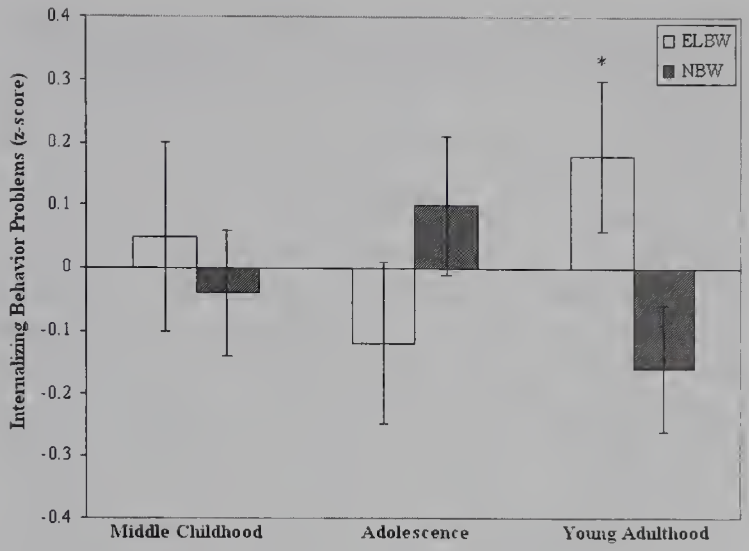

Figure 1. Standardized means (standard error bars) of internalizing problems in individuals born at extremely low birth weight (ELBW) and at normal birth weight (NBW) as children (ELBW: $n = 64$; NBW: $n = 80$) adolescents (ELBW: $n = 65$; NBW: $n = 74$), and young adults (ELBW: $n = 71$; NBW: $n = 82$; *between group difference, $p < .05$).

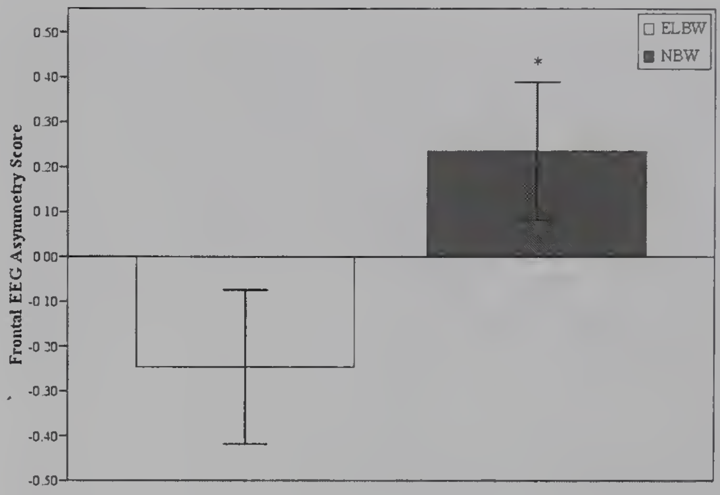

Figure 2. Mean difference (standard error bars) between individuals born at extremely low birth weight (ELBW; $n = 65$) and at normal birth weight (NBW; $n = 68$) on the pattern of resting frontal EEG alpha (8 to 13 Hz) asymmetry score (i.e., right frontal power *minus* left frontal power).

Note. EEG power is inversely related to activity so negative scores reflect greater relative right frontal EEG activity (*between group difference, $p < .05$).

adults showed a significant increase in internalizing behavior problems from adolescence ($M = -0.11$, $SE = 0.13$) to young adulthood ($M = 0.21$, $SE = 0.14$), $t(60) = 2.19$, $p < .05$, Cohen's $d = 0.28$, whereas NBW adults showed a significant decrease in internalizing behavior problems from adolescence ($M = 0.11$, $SE = 0.11$) to young adulthood ($M = -0.19$, $SE = 0.11$), $t(71) = 2.25$, $p < .05$, Cohen's $d = 0.29$. There were no significant between-group differences on internalizing behavior problems at middle childhood ($p > .05$) or adolescence ($p > .05$).

Resting frontal brain activity (EEG) at young adulthood. We predicted that adults born at ELBW would exhibit significantly greater relative right frontal EEG activity at rest compared with adults born at NBW. To test this prediction, we computed a frontal EEG asymmetry (right frontal power – left frontal power) metric. An analysis of covariance (ANCOVA) with group (ELBW, NBW) as the between-groups factor and concurrent depression ratings (CES–D measure) as a covariate was then performed on the frontal EEG asymmetry metric. Concurrent depression was covaried because concurrent mood is known to influence frontal asymmetry measures (see Beaton et al., 2008; Henriques & Davidson, 1990). This analysis revealed a significant main effect for group on resting frontal EEG asymmetry measure before, $F(1, 131) = 4.39$, $p < .05$, Cohen's $d = 0.37$, and after $F(1, 129) = 3.95$, $p = .05$, Cohen's $d = 0.36$, controlling for concurrent depression ratings (see Figure 2). As predicted, adults born at ELBW ($M = -0.25$, $SE = 0.17$) exhibited significantly greater relative right frontal EEG activity at rest compared with adults born at NBW ($M = 0.24$, $SE = 0.17$).

To understand the source of the asymmetry difference, a repeated measures ANOVA was computed with group (ELBW, NBW) and sex (male, female) as the between-groups factors, and region (frontal, central) and hemisphere (left, right) as the within-groups factors. The dependent measure was EEG alpha (8 to 13 Hz) power (μV^2). There were no significant main or interaction effects for sex, so this variable was collapsed in all subsequent analyses. The analyses revealed a significant Group × Region × Hemisphere interaction, $F(1, 131) = 4.59$, $p < .05$.

To decompose this interaction, we performed a separate ANOVA for each region with group (ELBW, NBW) as the between-subjects factor and hemisphere (left, right) as the within-subjects factor. The dependent measure was EEG alpha (8 to 13 Hz) power (μV^2). The analyses revealed a significant Group × Hemisphere interaction on alpha power only in the frontal region, $F(1, 131) = 4.39$, $p < .05$, confirming the frontal asymmetry difference above. The ANOVA with group and hemisphere as between-subjects factors on EEG power for the central region was not significant, ($p > .05$). Follow-up between-group and pairwise t tests computed on left and right frontal and central EEG power failed to yield any significant differences ($ps > .05$).

Baseline salivary cortisol at young adulthood. Table 3 presents the descriptive statistics on the salivary

Table 3

Descriptive Statistics for Extremely Low Birth Weight (ELBW) and Normal Birth Weight (NBW) Young Adults on the Salivary Cortisol Measures

	Group		
Measure	ELBW	NBW	
ln baseline salivary cortisol			
M (in ng/ml)	0.962	1.047	$t = -0.37$; $p > .05$
SE	0.150	0.171	
Average time of day of saliva collection			
M (in hr)	13:25	13:42	$t = -0.40$; $p > .05$
SE (in min)	0:29	0:17	

cortisol measures collected for the two groups. We predicted that ELBW adults would exhibit significantly higher salivary cortisol at baseline compared with adults born at NBW.

An ANCOVA with group (ELBW, NBW) and sex (male, female) as the between-groups factors was computed on the average baseline salivary cortisol measure. Time of day was included as a covariate in the salivary cortisol analysis, given that it is known to be related to cortisol levels (Daly & Evans, 1974). The analysis failed to reveal any significant main or interaction effects on the average natural log baseline salivary cortisol measure ($p > .05$).

Within-Group Analyses

Full sample analyses. Table 4 presents the Pearson correlations among the study measures for the full sample. As can be seen in Table 4, internalizing behavior problems at middle childhood and young adulthood ($r = .21$, $p < .01$) and at adolescence and young adulthood ($r = .33$, $p < .001$) were significantly correlated. As expected, children and adolescents who exhibited internalizing behavior problems were likely to display internalizing behavior problems as young adults.

Frontal EEG asymmetry at rest was related to concurrent internalizing behavior problems ($r = -.14$, $p < .06$) and baseline salivary cortisol ($r = -.20$, $p < .05$) at the young adult visit, although the former relation only approached statistical significance. As predicted, adults who exhibited greater relative right frontal EEG activity also tended to exhibit more internalizing behavior problems and higher baseline salivary cortisol levels contemporaneously.

Table 4

Pearson Correlations Among Study Measures Across Participants

Measure	1	2	3	4	5
1. Child internalizing problems	—				
2. Adolescent internalizing problems	.06	—			
3. Young adult internalizing problems	.21**	.33**	—		
4. Resting frontal EEG alpha asymmetry	.11	−.11	$-.14^{\dagger}$	—	
5. ln baseline salivary cortisol	−.01	.02	.04	−.20*	—

Note. Time of day was partialled out of all correlations involving the ln baseline salivary cortisol measure; EEG power is inversely related to activity so negative scores reflect greater relative right frontal EEG activity.

$^{\dagger}p < .06$. $^{*}p < .05$. $^{**}p < .01$.

Within-ELBW group analyses. We computed a series of within-group Pearson correlations within the ELBW group to examine if the two measures of stress vulnerability (i.e., resting frontal EEG asymmetry and baseline salivary cortisol) covaried in any systematic way with adverse early life events (e.g., birth weight, gestational age and respiratory support). Table 5 presents the within-group Pearson correlations among the study measures for the ELBW group.

As can be seen in Table 5, resting frontal EEG asymmetry was related to baseline salivary cortisol ($r = -.23$, $p < .05$) and birth weight ($r = .22$, $p < .05$) but not gestation age ($r = .03$, $p > .05$) or level of respiratory support at birth ($r = -.08$, $p > .05$). As predicted, ELBW adults who exhibited greater relative right frontal EEG activity at rest were likely to

5. ln baseline salivary cortisol	.01	.01	−.08	−.23*	—

Note. Time of day was partialled out of all correlations involving the ln baseline salivary cortisol measure; EEG power is inversely related to activity so negative scores reflect greater relative right frontal EEG activity.

$^{*}p < .05$.

exhibit higher salivary cortisol levels and lower birth weights.

Discussion

Pre- and perinatal risk factors such as being born at ELBW are presumed to influence brain–behavior relations. We examined internalizing behavior problems at middle childhood, adolescence, and young adulthood and patterns of resting frontal brain activity and baseline salivary cortisol in a sample of adult survivors of ELBW without major impairments. As predicted, we found that internalizing behavior problems significantly increased from adolescence to young adulthood among ELBW adults. Also as predicted, we found that ELBW young adults exhibited significantly greater relative right frontal EEG activity and more internalizing behavior problems than NBW controls. These findings were based, overall, on medium effect sizes and are consistent with a large corpus of literature suggesting a relation between right frontal brain asymmetry at rest and individual differences in stress vulnerability (see Coan & Allen, 2004; Davidson, 2000; Fox, 1991, for substantive reviews). Here, we extend these earlier findings on resting frontal EEG asymmetry as a stress vulnerability marker to a sample of adults born at ELBW without major impairments.

Why did differences in internalizing behaviors emerge in young adulthood and not earlier in development in ELBW adults? It is possible that there may be subtle influences on brain development due to adverse events early in life that may only manifest later in life. A recent study reported reduced fertility in adult survivors of extreme prematurity (Swamy et al., 2008). It is possible that adverse life events such as being born at ELBW may negatively impact brain–behavior relations among ELBW survivors only later in life at developmental transition points. One such developmental transition is young adulthood, which is characterized by psychosocial stressors such as the development of personal autonomy, striving for financial independence, career development, romantic relationships, and starting a family. This speculation needs to be tempered, however, in that a recent study noted pervasive behavior problems at 6 years of age in a sample of children born extremely premature (i.e., ≤ 25; Samara, Marlow, & Wolke, 2008), so behavioral problems may exist in extremely premature populations before adulthood. However, it is also important to note that the study by Samara et al. (2008) included a heterogenous sample of premature children likely including children with impairments. Such impairments may have contributed to their behavioral problems at younger ages. In the present study, we used a nonimpaired sample of adult survivors by design to mitigate some potential confounds due to impairment.

We also found that right frontal EEG asymmetry predicted concurrent internalizing behavior problems and cortisol levels across the full sample, and was significantly related to higher cortisol levels and lower birth weights among ELBW adults. These results are consistent with findings from studies of stress responses in humans (Buss et al., 2003) and nonhuman primates (Kalin, Larson, Shelton, & Davidson, 1998). Buss et al. (2003) found that human infants with high basal cortisol levels exhibited more freezing behavior in response to novel stimuli and greater relative right frontal EEG activity at age 6 months than infants with relatively lower levels of basal cortisol. Kalin et al. (1998) reported that nonhuman primate Rhesus monkeys who exhibited right frontal EEG activity also displayed high basal cortisol levels and fearful behavior. Taken together, these two studies suggest that (a) the pattern of resting right frontal EEG asymmetry is predictive of high baseline cortisol and stress responses, (b) this pattern emerges early in life, and (c) it plays a role in stress dysregulation that is conserved across mammals. The results of this study extend these findings to adult survivors of ELBW.

What does resting right frontal brain asymmetry and its relation to high cortisol reflect in ELBW? Over the last three decades, there have been more than 100 studies published that have examined patterns of frontal EEG activity during the processing of emotion and its role in explaining individual differences in affective style (see Coan & Allen, 2004, for a review). Overall, these studies suggest that individuals exhibit greater relative left frontal EEG during the processing of positive emotion (e.g., happy, joy), and greater relative right frontal EEG activity during the processing of negative emotion (e.g., fear, sadness). These patterns are evidenced across a variety of sensory modalities used to induce emotion, including visual, auditory, imagery, and olfactory senses. The findings from these studies also suggest that the pattern of resting frontal EEG activity emerges in the first months of postnatal life, remains moderately stable during development from childhood through adolescence and young adulthood, and predicts individual differences in affective style and risk for psychopathology. Individuals who present with tonic left frontal EEG activity tend to be social, extraverted, and outgoing, whereas individuals who exhibit tonic right frontal EEG activity are shy, anxious, and depressed.

It is possible that the pattern of greater relative right frontal EEG activity may constitute a mechanism predisposing individuals to difficulties in regulating stress, such as physical and mental problems. The pattern of right frontal EEG asymmetry observed in adult survivors of ELBW without major impairments might be due to adverse events early in life that shaped brain development in a relatively subtle way. Adverse early experiences are known to alter the development of the prefrontal brain regions, resulting in differences in right, but not left, adult prefrontal volumes in nonhuman primates (Lyons, Afarian, Schatzberg, Sawyer-Glover, & Moseley, 2002). The observed relation between right frontal EEG asymmetry and high cortisol in young adults born at ELBW may reflect a less obvious impairment due to this adverse event early in life, placing some young adults born at ELBW at risk for stress-related problems.

What may account for the lack of significant group differences on the salivary cortisol measure used in this study? Because the hypothalamic–pituitary–adrenal (HPA) axis is a dynamic system, it is possible that individuals, despite having similar basal salivary cortisol, may have different adrenocorticotrophic hormone (ACTH) levels. That is, although ELBW and NBW adults have similar cortisol levels (possibly for down-regulation of adrenal ACTH receptors), it is possible that ELBW participants have greater ACTH levels than controls. This hypothesis is in line with what others have reported in nondepressed adult survivors of childhood trauma (see Gunnar & Quevedo, 2007; Heim et al., 2000).

It also may be that adverse events early in life such as low birth weight only perturb the neuroendocrine system early in postnatal life on reactivity measures (see Wust et al., 2005) and not on basal measures. Or, by young adulthood, development and maturational control of this system may have been possibly repaired. The lack of group differences also might be related to issues of differential risk and resiliency and specificity of different stress vulnerability systems. The impact of ELBW may affect some, but not all, brain-based aspects of stress vulnerability in the same way. Some brain systems may be more vulnerable to the impact of adverse early life events than others.

Theoretical Implications

The findings from this study may be interpreted by, and have theoretical implications for, at least two models of development. One model of development is a brain "insult" hypothesis. It is possible that the events producing reduced birth weight also have perturbed select brain systems involved in the regulation of stress. Right frontal brain asymmetry and internalizing behavior problems may develop as a result of early brain insult in survivors without major impairments. We found that lower birth weight predicted right frontal brain asymmetry at young adulthood in ELBW survivors without impairments.

It is important to note, however, that there is an emerging literature suggesting another variation of a brain insult model. That is, the brain develops quite differently at extreme prematurity if the infant is raised extrauterine (e.g., cortical folding), resulting in the building of a different brain (e.g., Kapellou et al., 2006). This idea would predict that the impact is not specific to any one function, but influences general domains of functioning (e.g., language difficulties and school achievement) as has been shown for both very and extremely premature children (e.g., Wolke, Samara, Bracewell, & Marlow, 2008).

A second model that the present results may inform is a fetal programming hypothesis (Barker, 1995). Although controversial, Barker posited that stressful events during fetal development may "program" the developing brain for how it handles subsequent stress. A proposed mechanism is perturbations in the HPA axis due to early life events, which contribute to chronically elevated cortisol levels (Fall et al., 2002) and autonomic responses (Phillips & Jones, 2006). This early programming places individuals born extremely premature at risk for disease (Reynolds et al., 2001) and may influence individual differences in temperamental style (Pesonen et al., 2006). However, other studies have not found support for the fetal programming hypothesis. For example, Hanna et al. (1993) failed to find chronically elevated cortisol levels in infant survivors of ELBW. Hanna et al. argued that the relatively low levels of cortisol noted in infants born at ELBW may be due to the extremely premature brain's inability to recognize the stress of the illness or because of inadequate hypothalamic secretion of corticotropin-releasing hormone. If the fetal programming hypothesis were correct, we would have expected to find between group differences on salivary cortisol levels. As noted earlier, we did not find between-group differences on the cortisol measure. It might be that although there were no differences between the groups on cortisol, the differences might exist at the level of ACTH. However, we did not index ACTH, but future studies should consider doing so to test this hypothesis. The results of this study also suggest that stress early in life may alter fetal programming of specific stress vulnerability measures (e.g., resting frontal brain asymmetry), but not others (e.g., baseline salivary cortisol).

Limitations

There are at least four limitations in this study. First, we recorded resting frontal EEG asymmetry and baseline salivary cortisol levels on one occasion only. Accordingly, we do not have information on the stability of these measures or information on how frontal EEG asymmetry may or may not covary with internalizing behavior problems at earlier ages. Although empirical evidence suggests that the pattern of resting frontal brain activity is stable across time (Tomarken et al., 1992; Vuga et al., 2006; Vuga et al., 2008), it would be advisable to have repeated measures over time and earlier in postnatal development. Second, EEG is measured at the scalp and thought to reflect cortical electrical activity. However, we do not know the exact sources of the EEG signal so caution needs to be exercised in terms of interpretation of EEG findings as being specific to the cerebral cortex and a particular brain region. Future studies should consider the use of more dense arrays of EEG electrodes than used in the present study so that EEG source analyses can be performed. As well, measures of functional magnetic imaging might prove useful in combination with electrocortical measures to provide accurate spatial and temporal resolution of brain-based measures of stress vulnerability. Third, issues of causation cannot be ascertained. Although we presume that the adverse early life event of being born ELBW preceded the development of right frontal EEG asymmetry, we need to caution against making any kind of causal interpretation. It might be that right frontal EEG asymmetry is a consequence of ELBW, or a coexisting factor. Tracking brain development at pre- and early postnatal stages may hold some of the answers to questions of causality. Fourth, although we studied adult survivors of ELBW, there are other populations characterized by early adversity that are of interest. For example, survivors of VLBW (Hack et al., 2002), babies born small for their gestational age (Strauss, 2000), and babies born prematurely (Schothorst, Swaab-Barneveld, & van Engeland, 2007) are also known to be at risk for stress-related problems. In future studies examining multiple brain-based measures of stress vulnerability, these populations would further inform our understanding of the relation between early adversity and stress vulnerability.

Conclusions

Pre- and perinatal risk factors such as being born at ELBW are known to have a profound impact on a range of developmental processes. We found that internalizing behavior problems significantly increased from adolescence to young adulthood among ELBW individuals without major impairments. We also found that ELBW adults exhibited significantly more internalizing behavior problems and greater relative right frontal EEG activity at rest than NBW controls. Greater relative right frontal EEG activity was related to higher cortisol levels and lower birth weights among ELBW adults. Findings suggest that ELBW may negatively influence brain–behavior relations in subtle ways even among survivors without major impairments and that evidence of these influences may not emerge until young adulthood. ELBW may influence the development of right frontal brain asymmetry, a putative mechanism for difficulties regulating stress responses, which can manifest as internalizing behavior problems in young adulthood.

Late-Treated Phenylketonuria and Partial Reversibility of Intellectual Impairment

Scott D. Grosse
National Center on Birth Defects and Developmental Disabilities, Centers for Disease Control and Prevention

Individuals with late-treated phenylketonuria (PKU) not detected by newborn screening but who followed dietary treatment for at least 12 months before 7 years of age have intelligence quotient (IQ) scores that range from severe impairment to the low-normal range. Among adults with late-treated PKU in California, 85% of those who were born from 1961 to 1978 had IQ scores of 70 or above. Longitudinal studies with repeated cognitive assessments often show average changes in cognitive test scores as high as 20–45 points. Although the severe cognitive impairment associated with untreated PKU can in many cases be partially reversed with dietary treatment, prompt initiation of treatment following newborn metabolic screening is essential for optimal development and the prevention of disability.

Newborn screening for phenylketonuria (PKU), which began in the early 1960s (Levy & Albers, 2000), is a major public health success. PKU is an inborn error of metabolism caused by mutation in the phenylalanine (Phe) hydroxylase gene (*PAH*) gene resulting in elevated levels of Phe that can cause serious brain damage (Scriver, 2007).

The combination of early detection at birth and adherence to a low-Phe diet has been found to prevent all cases of intellectual disability among children born with PKU according to population-based studies that have linked newborn screening records with developmental disability surveillance systems (Bower, Leonard, & Petterson, 2000; Van Naarden Braun, Yeargin-Allsopp, Schendel, & Fernhoff, 2003).

It is commonly stated that almost all individuals with untreated classic PKU experience severe intellectual disability, typically with intelligence quotient (IQ) < 30 (Waisbren et al., 2007). However not all individuals with untreated PKU experience intellectual disability (Hanley, 2007), with certain individuals protected by the blood–brain barrier from high Phe levels passing from the bloodstream to the brain. Most, though, do experience some degree of impairment. One British study reported that 2 (15%) of 13 older siblings with untreated PKU among probands identified on the basis of developmental deficits had IQ scores > 70 and attended ordinary classes, but with markedly lower performance than their unaffected siblings (Smith & Wolff, 1974). A retrospective study from Australia of 56 individuals with classic PKU born prior to 1965 found that 75% of adults had IQ scores < 52 and 93% had IQ scores ≤ 85 (Ramus, Forrest, Pitt, & Cotton, 1999).

Treatment for PKU with a low-Phe diet that keeps blood Phe levels within the 2–6 mg/dl range prior to adolescence can eliminate all adverse effects on intellectual development (Stemerdink et al., 2000). However, it is very difficult to keep to a strict diet, and consequently, specific deficits, such as executive function, attention, and visual–spatial ability, remain problematic in many individuals with early and continuously treated PKU who have moderately elevated blood Phe levels (Brumm et al., 2004; Burgard, 2000; Diamond & Herzberg, 1996; Diamond, Prevor, Callender, & Druin, 1997).

The conventional wisdom holds that late-treated PKU results in "severe, irreversible mental

retardation'' (Abadie et al., 2001; Feldman, 1994) and that dietary treatment ''does not reverse preexisting damage'' (Seymour et al., 1997). ''Late-treated'' PKU commonly refers to children who were not detected through screening and were put on a low-Phe diet after 2–3 months of age, However, older studies noted that initiation of dietary treatment was often associated with substantial improvements in test scores (Berman, Waisman, & Graham, 1966; Knox, 1972; Waisbren, Schnell, & Levy, 1980). More recently, research conducted in California conclusively established that long-term outcomes among adults with late-treated PKU were often not as dire as expected (Koch et al., 1999; Trefz, Cipcic-Schmidt, & Koch, 2000). In interpreting these findings, Levy (2000) acknowledged ''some degree of reversibility'' following the late initiation of treatment, which he stated should be ''encouraging to families who have to cope with this tragedy.'' This does not detract from the importance of screening and prompt treatment to avoid needless brain damage.

Research on the neuropathology of brain impairment caused by PKU has yielded valuable information as to the mechanisms and anatomical manifestations of brain damage resulting from PKU. It has long been known that high Phe levels in the bloodstream alone do not explain brain damage, because individuals with the same elevated blood Phe levels show marked variations in the extent of neurological damage (Gizewska et al., 2003; Möller, Weglage, Wiedermann, & Ullrich, 1998; Möller et al., 2003; Weglage et al., 2002). The important new evidence is that interindividual variations in the blood–brain barrier appear to determine brain Phe levels and hence neurological outcomes (Gizewska et al., 2003; Koch, Moats, Guttler, Guldberg, & Nelson, 2000).

Magnetic resonance imaging (MRI) of the brains of individuals with PKU has revealed the characteristic presence of white matter (WM) abnormalities or alterations associated with elevated Phe levels (Anderson et al., 2004; Pietz et al., 1996). It has been demonstrated that these WM changes are partially reversible with short-term dietary treatment (Cleary et al., 1995; Thompson et al., 1993; Ullrich et al., 1994). Variations in WM lesions have not been reported to be statistically significantly associated with variations in IQ (Leuzzi et al., 2007; Pérez-Dueñas et al., 2006; Ullrich et al., 1994), although both children and adults with moderate WM abnormalities have been reported to have IQ scores lower by 6–14 points on average than those with no detectable WM lesions (Anderson et al., 2007; Koch et al., 2002). Crucially, WM abnormalities have been linked to specific neurological deficits such as in executive functions (Anderson et al., 2004; Anderson et al., 2007; Brumm et al., 2004), which have also been demonstrated to result from reduced dopamine activity in the prefrontal cortex in treated PKU children with insufficiently strict diets (Diamond, 1996; Diamond, Ciaramitaro, Donner, Djali, & Robinson, 1994; Diamond et al., 1997). Recent research suggests that neurological damage in late-treated PKU appears to be highly correlated with differences in the volume and distribution of gray matter in the brain (Pérez-Dueñas et al., 2006).

This article addresses the extent to which reductions in cognitive ability associated with late-diagnosed PKU are partially reversible by dietary modification. First, we review cross-sectional data on cognitive test scores and the prevalence of intellectual disability of late-treated individuals with PKU in relation to the age at which a low-Phe diet was introduced. Second, data on longitudinal changes in cognitive test scores among late-treated individuals are reviewed. No attempt is made to review the voluminous literature documenting the cognitive effects of age of initiation and adherence to therapy among individuals with early-treated PKU (see Burgard, 2000; Waisbren et al., 2007).

Method

Terms and Measures

Phenylketonuria is a type of hyperphenylalanemia (HPA), which is characterized by persistently elevated concentrations of the amino acid Phe in the blood. Persons with HPA are classified as having either classic PKU (blood Phe > 1200 µmol/L or 20 mg/dl), mild PKU (blood Phe 600–1200 µmol/L or 10–20 mg/dl), or non-PKU HPA (blood Phe 120–599 µmol/L or 2–10 mg/dl; Scriver & Kaufman, 2001). Mutations on the *PAH* gene, which result in deficiency of activity of a liver enzyme, PAH, are responsible for most cases of each type of HPA (Kaye & the Committee on Genetics, American Academy of Pediatrics, 2006). In this article, PKU refers specifically to classic phenylketonuria.

A low-Phe diet is one that avoids most foods with natural protein and incorporates Phe-free formula and/or medical foods with low levels of Phe. The purpose of a low-Phe diet is to maintain a blood Phe concentration for children within a target range, set at 120–360 µmol/L (2–6 mg/dl) in the United States (Koch et al., 2000). Metabolic control should be achieved as early as possible within the 1st month of life.

The terminology relating to cognitive impairment and disability is in a state of flux. Traditionally, the terms *mental retardation* and *mental handicap* were used to characterize individuals with cognitive abilities below the normal range and with limitations in adaptive functioning that began during childhood. Alternative terms, *intellectual disability* in the United States and *learning disability* in the United Kingdom, are increasingly preferred. In this article, *intellectual disability* (ID) refers to individuals with IQ or developmental quotient (DQ) scores ≤ 70 who are presumed to experience disability, and it is used as a substitute for *mental retardation*. An IQ score of 70 (or 75) is commonly used as a cutoff point for ID; individuals with IQ scores of 50–70 are classified as having mild ID and those with lower scores are said to have moderate, severe, or profound ID (Roeleveld, Zielhuis, & Gabreels, 1997). IQ scores of 70–84 are often classified as borderline and scores of 85 or higher are considered normal.

The cognitive tests used to calculate IQ scores are typically administered to children only at 4 years of age or older, whereas tests administered to younger children yield DQ scores. DQ and IQ scores are both standardized on the same scale, but DQ scores at or before 12 months of age primarily measure performance on sensorimotor tasks (Slater, 1997). DQ scores assessed at 2 years of age or later include verbal assessments and are more predictive of later IQ scores, although differences in test types still complicate the interpretation of changes in scores (Hack et al., 2005; Slater, 1997). For example, among preterm infants who had DQ < 70 at 20 months of age, 20% of those without neurosensory impairments had IQ < 70 at 8 years of age, compared with 62% of those who had a specific impairment (Hack et al., 2005). The gains were not primarily an artifact of the use of different tests, because individual test scores at both points at time were predictive of academic skills at 8 years of age.

Comparisons of cognitive test scores over time, whether between cohorts or longitudinal assessments for individuals, can be affected by general increases over time in IQ scores (Flynn, 1999). IQ tests are periodically recalibrated or renormed every decade or so, but the tendency for mean IQ scores to drift up over time means that a 2 *SD* difference from the mean IQ score might be > 75. However, this effect would not account for differential increases in test scores between groups. Also, there is no evidence that the percentage of children classified as having intellectual disability based on low IQ scores has decreased over time (Bhasin, Brocksen, Avchen, & Van Naarden Braun, 2006).

Inclusion and Exclusion Criteria

A search was undertaken to identify studies that assessed cognitive outcomes or neurological manifestations among individuals with late-treated PKU. Only studies in which individuals began dietary treatment before 7 years of age were included. Also, children had to have followed a low-Phe diet for at least 12 months to be included. Multiple search strategies were used, including systematic searches in PubMed and searches of citation lists. No restriction was placed on the date of publication for articles in English, Spanish, French, or German, and articles published after 2000 were included regardless of language of publication. A PubMed search conducted on April 18, 2007, for "phenylketonuria" and "late treatment" identified 76 studies, most of which dealt with treatment during adulthood, maternal PKU, or discontinuation of a low-Phe diet during adolescence rather than late initiation of treatment during childhood; 24 articles from this search met the inclusion criteria. Another search for "phenylketonuria" and "IQ" resulted in 179 hits, which included three studies of late-treated PKU not identified in the earlier search. Several other relevant studies were identified by clicking on the "Related Articles" link in PubMed for studies meeting the inclusion criteria. Finally, other articles were identified through searches of citation lists in other publications, including review articles.

Additional exclusion criteria were imposed for cross-sectional studies, owing to the relatively large number of studies compared with only a handful of studies reporting longitudinal cognitive assessments for late-treated individuals. First, because DQ scores in early childhood are less reliable than IQ scores measured in school-age children (Waisbren et al., 2007), only cross-sectional studies reporting IQ scores in children over 4 years of age were retained in this section. Second, only studies from North America, Western Europe, or other high-income countries were retained in this section because of the often poor quality of dietary control in the past in low- and middle-income countries. The quality of dietary treatment has a mediating influence on neurological outcomes in PKU, and the question of interest for this review consists of outcomes for late-treated individuals who receive high-quality management once diagnosed. Similarly, because individuals who were put on low-Phe diets beginning in the late 1950s or early 1960s typically had poorer dietary control than those who were treated in later periods, it is important to compare outcomes for successive birth cohorts.

Cognitive Assessments in Late-Treated PKU

Cross-sectional assessments. Challenges in interpreting data on cognitive assessments in individuals with late-treated PKU include different types of cognitive tests, ascertainment bias, and the quality of treatment provided. Ascertainment bias can affect studies in which children were detected as having PKU on the basis of testing prompted by developmental deficits, thereby biasing cognitive scores downward relative to children detected through biochemical screening (Birch & Tizard, 1967). Ascertainment bias continues to characterize many of the studies of late-treated PKU discussed here. Other potential biases include differences among families that might be associated with children's developmental outcomes, the timing of diagnosis, and the level of adherence to dietary restriction. Few of the studies reviewed here attempted to control for such potential confounding.

Even the quality of dietary control, which is the most important influence on developmental outcomes, was only partially controlled for in most published tabulations. Few of the studies reviewed here reported the degree of dietary control in sufficient detail that would allow for comparison of findings across studies. The reader should keep in mind that reported cognitive scores in late-diagnosed children could be biased downward relative to early-treated children if late-diagnosed children on average have less tightly controlled diets.

Prior to the introduction of dietary treatment and newborn screening, most individuals with PKU had IQ scores < 50 (Ramus et al., 1999). After dietary treatment was introduced in the 1950s, test scores began to improve and mean scores were often reported to be between 50 and 60. For example, McBean and Stephenson (1968) reported that 61% of 23 late-treated children in Scotland had IQ < 60. Two studies from Canada reported mean IQ scores of approximately 55 for children treated beginning between 6 and 24 months of age. Scriver, Katz, and Clow (1968) reported that 43 such children in Quebec had a mean IQ of 56 when tested at a mean age of 5 years, and Hanley, Linsao, and Netley (1971) reported a mean IQ of 55 for 30 such children in Ontario. If one includes in the latter calculations 20 children diagnosed after 24 months of age, mean IQ was 49.4. A subsequent analysis reported that for 27 young adults, mean age 23 years, whose treatment had began at an average of 24 months of age and lasted for an average of 4.5 years, mean IQ was 57.6 (Netley, Hanley, & Rudner, 1984).

Similarly, a 1980 study from Hannover, Germany, reported information on 3 individuals up to 25 years of age who had been diagnosed and begun treatment for PKU at 3.5–8.5 years of age and 3 others who were never put on a restricted diet (Schweitzer, Wolff, & Brodehl, 1987). It appears that all had been born prior to newborn screening being introduced. All 6 had IQ scores < 70; all 3 untreated individuals required residential care for severe disability as did 1 of 3 late-treated individuals. The mean IQ for the latter 3 was 55. However, another German study, from Hamburg, which involved 8 late-treated children with PKU, reported graphically raw scores on the Columbia Mental Maturity Scale. The average raw score was about 35, which was below the normal range, but for the subset of late-treated children who had good dietary control the mean score was about 45, within the normal range and not significantly lower than for early-treated children with good dietary control (Steinhausen & Börner, 1977).

A study from Japan reported data on 5 adults 24–33 years of age with late-detected PKU who participated in a MRI research study. All had been diagnosed at 1.5–2.75 years of age and subsequently put on a low-Phe diet (Izumi, Yamazaki, Nakabayashi, & Owada, 2006). One subject was reported to have severe mental retardation and 3 others were said to have mild or borderline mental retardation, but no criteria were given for these categories or IQ test results reported.

Other studies from high-income countries reported average IQ scores of approximately 70 in late-treated children born prior to the introduction of newborn screening. Among 5 children in Minnesota, United States, who were put on a low-Phe diet at 6–27 months of age, mean IQ at 7–11 years of age was 77 (Siegel, Balow, Fisch, & Anderson, 1968). Two larger studies yielded more representative data. First, Dobson et al. (1968) reported that 64 U.S. and English children who were placed on a low-Phe diet at 4–36 months of age and assessed at age 7 years had mean IQ of 69, which did not vary by age of initiation of treatment. Second, Smith et al. (1978) reported that 43 late-treated children in England and Germany who had been placed on a strict diet for at least 3 years after 4 months of age had mean IQ of 71 when assessed at a mean of 12 years of age.

In the United States, Legido et al. (1993) reported IQ results for 12 individuals with late-treated PKU seen at a Philadelphia clinic, all except one of whom had been born prior to newborn screening. All had been started on a low-Phe diet after age 3 months and had gone off the diet at a mean age of 7 years. Although all had been identified as having PKU as part of a workup for developmental delay, mean IQ in adolescence was 72.8, and 4 (33%) had final IQ < 70. Age of diagnosis was reported to be a significant influence on final IQ, which was 80.8 for 5 who had been put on a low-Phe diet before 10 months of age and 67.1 for 7 whose treatment started later. The authors did not comment on the contrast between their finding of an effect of age of treatment and the null finding of Dobson et al. (1968). It is unclear whether there were other characteristics of the children treated before 10 months of age (later birth cohort?) that might help to account for this finding.

Findings from these early, pre-1965 cohorts are heterogeneous. Two Canadian studies with a total of 73 subjects (Hanley et al., 1971; Scriver et al., 1968) reported a mean IQ of approximately 55, as did a small German study with 3 late-treated subjects (Schweitzer et al., 1987). In contrast, four studies with data on a total of 124 late-treated subjects from the United States, England, and Germany reported a pooled mean IQ of 70.2 (Dobson et al., 1968; Legido et al., 1993; Siegel et al., 1968; Smith et al., 1978).

Studies that reported cognitive assessments among children with PKU who were born in high-income countries after the mid-1960s are summarized in Table 1. Campistol Plana, Alvarez Dominguez, Riverola de Veciana, Castillo Rivera, and Giner Soria (1991) reported that of 7 children 4–14 years of age with late-treated PKU who were born in Catalonia, Spain, 1976–1985, and diagnosed at 1.5–8 years of age, 5 who were on a low-Phe diet had a mean IQ score of 63 compared with a mean IQ of 48 for 2 children who were untreated. A subsequent report from the same Barcelona hospital presented information on a subset of 11 patients with tremor among 18 adult patients (19–37 years of age) with late-treated PKU. Of those 11, 8 had been placed on a low-Phe diet at 0.3–6.75 years of age and had a mean IQ score of 69 (range 50–103; Pérez-Dueñas et al., 2005). Seven patients without tremor, whose individual scores were not listed, had IQ scores higher by 10 points on average.

A study from Andalucía, Spain, by Lluch Fernández et al. (1988) reported data on 9 children with late-treated PKU who were diagnosed at 0.5–8 years of age and born 1968–1980. When assessed in 1985 at 5–18 years of age, 7 (78%) had IQ scores ≤ 70, and the other 2 had scores above 80. However, one third of the children were on uncontrolled diets, and scores were not reported separately for the children with low-Phe diets. All 9 children were identified with PKU after being diagnosed with developmental delays, which raises the problem of ascertainment bias.

In Italy, investigators analyzed cognitive data on 11 late-treated subjects with PKU who were diagnosed during 1965–1992 at 0.8–4.5 years of age and remained on a low-Phe diet for at least 4 years, in addition to a 2-year-old child who had only recently been put on a low-Phe diet (Leuzzi, Trasimeni, Gualdi, & Antonozzi, 1995). These subjects were recruited to participate in an MRI study and were not necessarily representative. Three (27%) of the 11 late-treated subjects who had been treated for at least 4 years had IQ > 85, 4 (36%) had IQ 56–65, and 4 (36%) had IQ ≤ 50. Although the

Table 1
Mean IQ Scores and Percentages ≤ 70 and ≤ 50 for Late-Treated Individuals With PKU Following a Low-Phe Diet for Several Years

Note. IQ = intelligence quotient; NR = not reported; low-Phe diet = low-phenylalanine diet; PKU = phenylketonuria.

authors did not report this, there was an indication of a likely cohort effect. The 7 late-treated individuals who were ages 17.5–25 years at the time of the final assessment all had IQ < 70, many of whom were born prior to the introduction of newborn screening. In comparison, only 1 (25%) of 4 children, aged 6.8–15 years who had been treated for multiple years had IQ < 70, and their average IQ score was 86. All of the late-treated individuals had initially been diagnosed with cognitive deficits, which reflects ascertainment bias. Several of those children subsequently had cognitive tests in the normal range, as noted by the authors.

A large U.S. study with data for 49 late-treated adults in California who were followed to age 18 years (Koch et al., 1999) provides data that allow for an analysis of differences in IQ scores across birth cohorts (Table 2). Overall, 27% of those with IQ scores measured had an IQ ≤ 70, 50% among those born in 1960 or earlier and 14%–16% among those born after 1960. Among the post-1965 birth cohort, IQ scores below 70 were found only among those diagnosed at 3 years of age or older. Mean adult IQ scores showed a similar pattern, 72.9 for the 1951–1960 cohort and 84.1–84.3 for the post-1960 cohorts. Among the post-1965 cohort, a mean IQ of 76.2 was observed for 5 subjects diagnosed at 3–7 years of age compared with a mean IQ of 92.0 for 5 subjects diagnosed at 1–2 years of age. Individuals who began treatment after 3 months but before 12 months of age had a mean adult IQ of 91.8 in the 1961–1965 birth cohort and 97.3 in the 1965–1978 birth cohort. The IQ scores reported in this study are substantially higher than those for contemporary cohorts reported in Japanese and Canadian studies of adults with late-treated PKU who had been treated as young children (Izumi et al., 2006; Netley et al., 1984). This might reflect differences in the strictness of dietary control achieved across populations and centers. The California findings indicate cognitive outcomes in late-treated PKU that are achievable with rigorous dietary control.

Table 2

Mean IQ Scores and Percentages < 70 Among 49 Adults With Classic PKU Born 1951–1978, Diagnosed After 3 Months of Age, and Followed Up at the University of California at Los Angeles (Koch et al., 1999)

		Age at diagnosis			
Birth year		< 1 year	1–2 years	3 years+	Any age
1951–1960	Mean	69.0	78.4	59.0	72.9
	IQ < 70 (%)	100	36	75	50
	Proportion	1/1	4/11	3/4	8/16
1961–1965	Mean	91.8	79.2	75.8	84.3
	IQ < 70 (%)	0	20	40	16
	Proportion	0/9	1/5	2/5	3/19
1966–1978	Mean	97.3	92.0	76.2	84.1
	IQ < 70 (%)	0	0	40	14
	Proportion	0/4	0/5	2/5	2/14
All years	Mean				
	IQ < 70 (%)	7	24	50	27
	Proportion	1/14	5/21	7/14	13/49

Note. IQ = intelligence quotient; PKU = phenylketonuria.

Longitudinal assessments. The methodological challenges in interpreting longitudinal assessments differ from cross-sectional assessments. Ascertainment bias is less of an issue. Only children with an initial developmental delay contribute data relevant to the question of partial reversibility of delays. The quality of dietary control and its duration are important. Short- and medium-term assessments provide limited information because it might take several years on a low-Phe diet for improvements to fully manifest themselves.

Problems of comparability of cognitive assessments are a particular challenge for longitudinal assessments. Studies that report changes in mean test scores for different groups based on treatment and age of initiation of a low-Phe diet are more informative because the between-group comparisons allow one to draw inferences unaffected by test type or the Flynn effect. Because valid IQ scores cannot be obtained from very young children, assessments of changes over time involve the comparison of DQ and IQ scores. Only DQ scores assessed after 12 months of age are included in this section because scores under 12 months do not measure mental development (Slater, 1997). Waisbren et al. (2000) compared DQ scores measured at 2 years of age with the Bayley Scales Mental Index to those assessed at 4 years of age with the McCarthy Scales General Cognitive Index for children of mothers with HPA and a control group and reported that mean DQ decreased from 96 to 85 for the former and from 114 to 110 for the latter. Waisbren and Azen (2003) reported IQ scores for the same cohort measured at 7 years of age; mean IQ scores were 90 for the HPA offspring and 106 for the control group. Despite differences in test types, neither group showed significant changes over time in cognitive test scores.

Older studies often reported appreciable increases in cognitive test scores among late-diagnosed children with PKU. Fuller and Shuman (1969) commented that some children put on a low-Phe diet at 3 years of age improved sufficiently to outperform other children who had been placed on a low-Phe diet soon after birth. Knox (1972) summarized data on changes in either DQ or IQ after at least 3 years of treatment for five groups of children for whom the mean age of diagnosis was 10–30 months, with mean changes ranging from barely imperceptible to over 25 points. McBean and Stephenson (1968) reported longitudinal assessments in 3 children in Glasgow, Scotland, treated beginning at 35–42 months of age. The increases in IQ scores ranged from 25 to 41 points (from 55 to 96, from 25 to 62, and from 52 to 77). One other child treated at 67 months of age showed no change in IQ scores.

Berman et al. (1966) reported repeated assessments for 22 treated and 5 untreated children with PKU seen at a Wisconsin clinic 1957–1964. The mean change in test scores was +7.5 points for the treated group, compared with a change of −8 points for those who were untreated. For 15 children who were at least 6 months of age at the initial assessment and with a final assessment more than 12 months after the initial assessment, the mean change was +11.6 points, with a range from −3 to +35 points.

A study in East Germany involving 19 children who were diagnosed with PKU after 6 months of age and followed for an average of 5 years while on a low-Phe diet reported that DQ scores for 7 children who were more than 24 months of age when first treated increased by an average of 13.4 points before the children went off the diet ($p < .05$; Theile, Bührdel, & Graustein, 1976). No significant increase in DQ scores occurred among 12 children put on the diet before age 24 months, but these children had a lesser degree of impairment. Only 5 of 12 had initial DQ ≤ 30 compared with 5 of 7 children in the older group.

A long-term study of changes in cognitive test scores conducted at the University of California at Los Angeles reported cognitive assessments at both age of diagnosis and during adulthood for 30 individuals born 1951–1978 and diagnosed at 12 months of age or later who followed a low-Phe diet (Koch et al., 1999). Changes in test score for the 29 subjects for whom test scores at time of diagnosis were available ranged from 29 to 70. The mean change in test scores between diagnosis and adult assessment was 24.4 (range = 2–48 points) for 12 subjects born 1951–1960, 20.8 (range = 4–34 points) for 8 subjects born 1961–1965, and 36.0 (range = 15–56 points) for 10 subjects born 1965–1978. In each birth cohort, there was no significant difference in mean increments in test scores between those diagnosed at 1–2 years of age and those diagnosed after 2 years of age.

In Mexico City, investigators followed 5 children with PKU who began treatment after approximately 12 months of age (Carnevale, Velazquez, Ruiz, & Del Castillo, 1979). The investigators used the Gesell and Terman-Merrill to measure DQ or IQ; the results were presented graphically. Four of the children followed a low-Phe diet for at least 12 months. The increments were approximately 30, 25, 5, and 30 points; the last observation was for a child who had a DQ of about 35 when diagnosed at 3.5 years of age and had an IQ of about 65 when retested at 5 years of age. Conversely, a child who never established dietary control continued to have a DQ under 20.

In Hamburg, Germany, investigators followed 8 late-treated children who were put on treatment after 6 months of age and conducted repeated assessments using the Columbia Mental Maturity Scale (Steinhausen & Börner, 1977). Only raw results were reported and they were presented graphically. The mean score increased between the first and third measurements by about 6 points, from 27 to 33, which on a scale of 100 would be approximately twice as large. Also, the majority of the late-treated children had poorly controlled diets. Longitudinal results were not reported separately for the children who experienced good dietary control, but their test scores were much better, about 45 on average.

Yang et al. (1999) reported on the experience of 161 late-diagnosed children seen at a hospital in Beijing, China, who were on a low-Phe diet for anywhere from 3 months to 6 years. Most (73.3%) showed marked improvement, including 21.1% (36 of 161) who had a final IQ score of 75 or greater. The authors noted that the low-Phe diet available at the time was suboptimal. Indeed, children with PKU in that center whose treatment was initiated before age 3 months were no more likely to have IQ > 75 (Yang et al., 1999).

Two publications from another Beijing hospital also contained longitudinal follow-up data. First, Yu et al. (2003) reported that 81 children with late-treated PKU were maintained on a low-Phe diet for 10–18 months. Their mean Gesell IQ score was reported to have increased from 61 to 72 ($p < .05$). A subsequent publication from the same institution reported detailed assessments of a small group of 19 children with late-treated PKU who at ages 1 through 6 years were given a low-Phe diet and followed for an average of 9 months (Wang, Zhou, & Yu, 2006). These children were assessed before and after with both Gesell's intelligence scale and MRI. The following calculations are based on Table 1 of Wang et al. (2006). The mean cognitive test score increased by 15.8 points, from an initial mean of 44.6 to a final mean of 60.4 ($p < .01$). Individual children had gains ranging from 6 to 32 points. Most showed WM lesions that underwent significant decline following dietary treatment, although this could have been coincidental.

Other investigators have reported longitudinal assessments for case reports. For example, Holmgren, Blomquist, and Samuelson (1980) reported that a Swedish child with PKU was put on a low-Phe diet for 8 years beginning at age 8 years and the child's IQ score rose by 41 points, from 59 to 90. Investigators in Poland, where screening for PKU began in the 1980s, reported long-term assessments on 2 late-diagnosed siblings with the same *PAH* genotype (Gizewska et al., 2003). The older sibling was diagnosed at 4.5 years of age, with an IQ of 63. After 14 years of dietary treatment, this child's IQ had increased by 44 points, to 107. The younger sibling, diagnosed and put on treatment at 11 months of age, was unable to be tested with an IQ test at 4 years of age because of severe impairment, with no subsequent improvement through 22 years of age. The 2 siblings had similar blood Phe levels, but the brain Phe levels differed (Gizewska et al., 2003).

Discussion

The conventional wisdom that PKU uniformly results in severe intellectual disability in the absence of newborn screening properly should refer to outcomes in the absence of treatment during childhood. Children who are put on a low-Phe diet when diagnosed often reach adulthood with lesser degrees of impairment. Older studies that reported mean IQ scores in the 50s among individuals with late-treated PKU were subject to ascertainment bias (Birch & Tizard, 1967); other studies from high-income countries reported mean IQ scores of approximately 70 (Dobson et al., 1968; Legido et al., 1993; Siegel et al., 1968; Smith et al., 1978). Most children missed by universal newborn screening programs in high-income countries in recent decades and described in the scientific literature have had IQ scores in the borderline to the low-normal range (Campistol Plana et al., 1991; Koch et al., 1999; Leuzzi et al., 1995; Trefz et al., 2000).

The level of cognitive test scores for late-treated individuals with PKU born in low- or middle-income countries is often much lower than for those born in high-income countries who were missed by newborn screening. Thus, for example, 5 late-treated children with PKU in Turkey were all reported to have IQ < 50 (Ozalp et al., 1994). Similarly unfavorable results were reported from East German (Wässer, Theile, Graustein, & Bührdel, 1979) and Romania (Popescu et al., 2000). Likewise, the absolute levels of test scores in the longitudinal assessments from East Germany (Theile et al., 1976), Mexico (Carnevale et al., 1979), and China (Wang et al., 2006; Yang et al., 1999; Yu et al., 2003) were relatively low, despite favorable changes during the course of treatment.

Longitudinal data on cognitive test scores provide evidence of partial reversibility of the cognitive impairment associated with late-diagnosed PKU. Studies that have conducted repeated developmental assessments of late-treated PKU subjects have reported marked improvement in standardized test scores in many cases, although this is highly variable among individuals. This is not a new finding but reinforces observations first reported by Berman et al. (1966), "While phenylketonuric children showed significant gains in developmental rate and IQ during dietary treatment, the fact that they did not attain rates as high as their unaffected siblings suggests that some of the effects of PKU continue to be operative even when blood Phe levels are controlled." More recent studies have demonstrated that some individuals achieve gains in test scores of 20–45 points, although others manifest no improvement despite continued treatment (Gizewska et al., 2003). In comparison, longitudinal studies of early-treated PKU subjects, as well as unaffected individuals, have reported that test scores were stable or, when dietary compliance became more relaxed, in some cases declined (Burgard, Schmidt, Rupp, Schneider, & Bremer, 1996). None of the studies reviewed here discussed the potential contribution of behavioral and other nondietary interventions to the achievement of improved cognitive test scores among many individuals with late-treated PKU.

The pattern of longitudinal increases in standardized test scores among children with late-treated PKU appears to resemble that of children born extremely low birth weight, a finding, which has been suggested to reflect the plasticity of brain development in early to mid-childhood (Hack et al., 2005). The latter study found that among children with developmental delay at 20 months of age, 20 (44%) of 45 with intact neurosensory function had IQ scores ≥ 85 at 8 years of age, as did 8 (24%) of 33 with neurosensory impairments. Long-term follow-up of children with low DQ scores is needed before a definitive assessment can be made. A DQ score of 50 for a young child does not mean that the child will necessarily have intellectual disability. On the other hand, although there may be partial reversibility of cognitive deficits, late-treated PKU is associated with irreversible neurological damage that seriously reduces individual abilities.

The improvement in cognitive test scores often observed with continued treatment of late-diagnosed children with PKU should give some degree of hope to parents of children who unfortunately missed being detected through newborn screening (Levy, 2000). It in no way reduces the urgency of universal screening and prompt initiation of treatment, which is essential for optimal development. A delay of 4 weeks in starting treatment has been associated with a loss of several IQ points at age 4 years (Smith, Beasley, & Ades, 1990). Reduced IQ scores represent an unnecessary and avoidable loss of cognitive and economic potential. Other aspects of neurodevelopment, such as visual–spatial executive functions, are often compromised among individuals with PKU whose blood Phe levels were not strictly controlled, even those with IQs in the normal range (Burgard, 2000; Diamond & Herzberg, 1996; Waisbren, Brown, de Sonneville, & Levy, 1994). Early diagnosis in combination with intensive treatment is the only means to minimize neurological damage caused by PKU. Promising alternative treatments to dietary Phe restriction include large neutral amino acid administration and supplementation with the PAH cofactor tetrahydrobiopterin (BH_4; Scriver, 2007).

Placement in Foster Care Enhances Quality of Attachment Among Young Institutionalized Children

This study examined classifications of attachment in 42-month-old Romanian children ($N = 169$). Institutionalized since birth, children were assessed comprehensively, randomly assigned to care as usual (CAU) or to foster care, and compared to family-reared children. Attachment classifications for children in foster care were markedly different from those in the CAU. Importantly, children placed in foster care before 24 months were more likely to have secure attachments and if placed earlier were less likely to have disorganized or insecure-other attachments. Cognitive status predicted greater likelihood of organized attachment in the CAU and greater likelihood of secure attachment in the foster care and never-institutionalized groups. Foster care is an important intervention to reduce the adverse effects following early deprivation.

Attachment theory implies that the formation of a preferred attachment between infant and parent reflects the activity of ''experience expectant'' neural systems (Greenough, Black, & Wallace, 1987). Specifically, our species has evolved in such a way as to expect that infants will be cared for by a capable caregiver, one who can ensure survival. Accordingly, only in the most extreme conditions of rearing do attachments fail to develop, such as in children who have been severely neglected (Boris et al., 2004; Zeanah et al., 2004) or in those raised in institutional settings (Smyke, Dumitrescu, & Zeanah, 2002; Tizard & Rees, 1975; Zeanah, Smyke, Koga, Carlson, & the BEIP Core Group, 2005). In both instances, the young child's ability to form selective attachments is limited by aberrant environmental conditions. Even in these atypical settings, however, attachment to a preferred caregiver seems often to occur, indicating a ''hard-wired'' propensity for the young child to become attached.

On the other hand, the type or quality of attachments a young child forms seems to reflect neural processes that are ''experience dependent'' (Greenough et al., 1987). That is, attachment theory posits that the young child constructs attachment relationships that reflect the child's experiences with particular caregivers. Quality of attachment is typically assessed by using the Strange Situation procedure (SSP; Ainsworth, Blehar, Waters, & Wall, 1978) that examines individual differences in the organization of attachment and exploratory behaviors. As a child forms an attachment to an adult caregiver, experiences with that adult seem to relate to the type or quality of that attachment. This model is supported by various lines of evidence about quality of attachment.

In addition to the fact that children may develop different types of attachments to different caregivers, a large number of studies have linked parental characteristics to infant attachment, including parents' sensitive behavior toward the infant, state of mind with regard to attachment, insightfulness, and reflective functioning (De Wolff & van IJzendoorn,

---

The Bucharest Early Intervention Project (BEIP) was funded by the John D. and Catherine T. MacArthur Foundation Research Network on Early Experience and Brain Development (Charles A. Nelson, network chair). We thank our dedicated BEIP research staff as well as Hermi R. Woodward and Sebastian F. Koga. We are very grateful to the children and caregivers who have participated in the BEIP.

1997; Koren-Karie, Oppenheim, & Doley, 2002; Slade, Sadler, & Mayes, 2005; van IJzendoorn, 1995).

Nevertheless, the strongest evidence to date demonstrating that the specific quality of the child's attachment depends upon parental characteristics comes from various interventions in which changing parents' behaviors or their states of mind have led to changes in the quality of attachment of the child to that caregiver. These interventions have included impoverished mothers and infants (Heinicke, Fineman, & Ruth, 1999), mothers and their temperamentally difficult (van den Boom, 1994) or highly reactive (Klein Velderman, Bakermans-Kranenburg, & Juffer, 2006) infants, maltreated infants and their mothers (Cicchetti, Rogosch, & Toth, 2006; Toth, Maughan, & Manly, 2002), and foster mothers and their infants (Dozier, Grasso, & Lindhiem, 2007; Fisher & Kim, 2007). Impressively, these studies have shown uniformly better quality of attachments between infants and caregivers in intervention rather than endangered or stressed control groups.

There is also evidence about the ability of infants and toddler raised in institutional settings to recover from their early adversity and form healthy attachments. Some of the young children being raised in institutions have no attachments to their institutional caregivers (Smyke et al., 2002; Tizard & Rees, 1975; Zeanah et al., 2005), and a majority have compromised attachments, as reflected by the prevalence of disorganized and other atypical classifications of attachment (Vorria et al., 2003; Zeanah et al., 2005).

An early descriptive study that followed children after they had been removed from an institution and placed in foster care was conducted by Goldfarb (1943). He described 10- to 14-year-old children who had lived in institutions for their first 3 years of life as withdrawn and removed from their foster parents and caseworkers. He concluded that children who had been institutionalized in the early years of life could not form attachments.

A subsequent study with improved methodology reached a different conclusion. Tizard and her colleagues (Hodges & Tizard, 1989; Tizard & Hodges, 1978; Tizard & Rees, 1974, 1975) studied 65 children abandoned at birth due to poverty and placed in residential nurseries in London. Between ages 2 and 4 years, 15 of the children were returned to their biological parents, 24 were adopted, and 26 were still being reared in the residential nurseries. At age 4 years, the children were evaluated. Although the majority of the 26 children who remained in institutions at age 4 years showed serious disturbances of attachment, this was not true for either the adopted or the returned groups. In fact, 80% of the adoptive parents reported that their children had become attached to them within 1 year, and the majority reported that the children were deeply attached. Nevertheless, even in the adoptive group, which had a more favorable outcome than the other two groups across all measures and ages studied, some children displayed signs of indiscriminate behavior, that is, lack of reticence about approaching, interacting with, and going off with a stranger. None of the comparison group of children who had never been institutionalized showed indiscriminate behavior. Thus, Tizard's findings suggested more plasticity in attachment than Goldfarb (1943) had believed possible.

MacLean (2003) has pointed out correctly that one reason for the discrepancy may be that the children Goldfarb (1943) studied experienced more severe privation than the children Tizard and her colleagues (Hodges & Tizard, 1989; Tizard & Hodges, 1978; Tizard & Rees, 1974, 1975) studied. This was reflected both in descriptions of the institutional caregiving practices and in the IQs of the two groups. The children in the Tizard study who lived in residential nurseries had IQs in the average range, whereas the children in the Goldfarb study were delayed in all domains. Nevertheless, the main problem with these studies is that the measures of attachment they used were neither standardized nor derived from behavioral observations. More recent studies have addressed these shortcomings by studying attachment in preschool children.

Marcovitch et al. (1997) compared fifty-six 3- to 5-year-old Canadian children who had been adopted out of Romanian institutions before 6 months of age to those who had been adopted after 6 months of age, as well as a group of never-institutionalized Canadian comparison children. They found that secure attachment was observed less often (30%) controlling/insecure-other more often (42%).

Chisholm (1998) studied children adopted into Canada after having spent at least 8 months in a Romanian institution (*n* = 46), children adopted into Canada from Romania at < 4 months of age (*n* = 30), and a Canadian-born comparison group matched on age and sex to the first group (*n* = 46). Attachment at 39 months postadoption was assessed with a home-based version of the SSP and coded with the Preschool Assessment of Attachment (Crittenden, 1992). Children who had spent 8 months or more in institutions were less likely to be securely attached than the other two groups of children, 37% versus 66% of those adopted after 4 months or less versus 58% of the Canadian children. In addition, there were more atypical insecure attachments in the group who had spent 8 months or more in institutions, 32.6% versus 3.7% of the < 4 months group and 6.9% of the Canadian children.

O'Connor, Marvin, Rutter, Olrick, and Britner (2003) studied attachment, using a within-the-home SSP in 111 four-year-old children adopted out of Romanian institutions into the United Kingdom and compared them to 52 nonmaltreated children adopted within the United Kingdom at < 6 months of age. They found that 55.1% of the children adopted within the United Kingdom were securely attached, with 4.1% disorganized-controlling and 16.3% insecure-other. In contrast, the Romanian children adopted out of institutions prior to 6 months of age were 41% secure, 9.8% disorganized-controlling, and 38.5% insecure-other. Of the children adopted after 6 months from institutions, only 33.3% were secure, whereas 7.7% were disorganized-controlling and 51.7% were insecure-other.

Taken together, these results indicate that children do form attachments following early deprivation, but subsequent attachment relationships are less likely to be secure and more likely to be atypical (disorganized-controlling or insecure-other). Organized insecure patterns of attachment (avoidant, ambivalent, and dependent) do not appear to be increased in children with institutional rearing.

Adoption studies such as these, informative as they are, also have limitations. These studies include only children who were selected intentionally rather than randomly, and they involve changes for the child not only from institutional care to family care but also changes in spoken language and culture.

In part to address these limitations, we initiated the Bucharest Early Intervention Project (BEIP; Zeanah et al., 2003). This is the first-ever randomized controlled trial of foster care as an alternative to institutional care. The BEIP was begun in the fall of 2000, involving 136 children living in institutions in Bucharest, Romania. They were recruited between the ages of 6 and 31 months, assessed comprehensively, and then assigned at random to foster care or to continued institutional care. They were reassessed at 30, 42, and 54 months of age, and the children in foster care were compared to children who received continued institutional care and to a group of never-institutionalized children who were recruited from pediatric clinics and living with their families. In this report, we report on differences in attachment in the children at 42 months.

Specifically, we examined the following questions. Did placement of young children being raised in institutions into families increase security of attachment and decrease atypical patterns of attachment at 42 months of age compared to children who received ongoing institutional care? Did age at placement in foster care affect the likelihood of children developing secure or organized attachments at 42 months of age? Did factors such gender, ethnicity, developmental quotient (DQ), or age at placement moderate the effects of intervention on security or organization of attachment?

Method

Participants

Three groups of children participated in this study. They were all participants in the BEIP, a longitudinal study aimed at examining recovery from early deprivation (Zeanah et al., 2003) through placement in foster care as an intervention to address the effects of early institutionalization. All of the children < 31 months of age who were cared for in the six institutional settings in Bucharest, Romania at the beginning of the study ($n = 187$) were assessed for participation in the BEIP. Exclusion criteria for the study included medical conditions such as genetic syndromes, signs of fetal alcohol syndrome, and microcephaly. A total of 51 children were excluded from the study. The sample consisted of children ($n = 136$) who had been abandoned very early in their lives and placed in institutions. After extensive baseline assessments (see Smyke et al., 2007, for a full description), the 136 institutionalized children were randomized into the continued care as usual including institutionalization group (care as usual group [CAUG]; ($n = 68$) or to the BEIP foster care group (FCG; $n = 68$). Randomization was accomplished by assigning a number to each of the 136 study children. These numbers (1–136) were placed in a hat and then drawn at random from the hat. The first number drawn was assigned to the CAUG and the second number was assigned to the FCG, with this pattern repeated until all 136 numbers had been drawn. There were two sets of twins in the study. The twins' numbers were placed on the same piece of paper and each set of twins was placed together.

A third group of children comprised children reared in their families and recruited from pediatric clinics in Bucharest (NIG; $n = 72$). This group was not randomly assigned and served as a comparison group. Figure 1 illustrates the flow of participants through the study. All children were originally recruited when they were between 6 and 31 months of age. Data presented in this study were obtained during the course of the 42-month assessment, which occurred 11–36 months after randomization. As noted in Figure 1, there were 57 CAUG, 61 FCG, and 51 NIG who completed SSPs with usable data at 42 months.

For ethical and legal reasons, we did not interfere with any decisions regarding children's placements, leaving those decisions to Romanian child protection officials. The one exception was that we ensured that no child randomized to foster care would be readmitted to institutional care during or after the study. Between the baseline and 42-month assessments, a number of children changed status (see Figure 1). In the following analyses, we followed an "intent-to-treat" approach, so that children were assessed in their original group (CAUG or FCG), regardless of their status at 42 months.

Additional details regarding sample recruitment are available (Zeanah et al., 2005). Table 1 provides demographic information for the study sample. As noted in Table 1, the ethnic distribution of the randomized groups (CAUG and FCG) is similar (Roma ~33%) but it differs from the comparison group. The overrepresentation of children of Roma heritage in institutions has been noted previously (Stephenson et al., 1993) and probably reflects the impoverished circumstances of many Roma. Early reports suggested that almost half of the young children in Romanian institutions were of Roma heritage (Stephenson et al., 1993), despite the estimates that Roma account for < 10% of the population of Romania.

BEIP Foster Care Intervention

Foster care was conceptualized as an intervention to address the effects of institutionalization on young children. When the project began in 2000, there were almost no foster homes in Bucharest, and they primarily had been used by adoption agencies to prepare children for the transition from institution to adoption. BEIP created a network of 56 foster homes in Bucharest. Foster parents were recruited, completed a background check, and trained by Romanian trainers using a manual derived from similar manuals used in the United States. Foster parents were considered full-time employees and received a salary and benefits. This was in contrast to the United States, where foster parents usually receive board payment for each child and do not receive payment if no child is in their home.

Foster parents received support from and were monitored by BEIP social workers who visited with them regularly. Social workers assisted foster parents in managing challenging postinstitutional behavior and organized a support group for foster parents early in the project. Importantly, social workers supported the foster parents in the establishment of warm, supportive, and committed relationships with their young foster children. BEIP foster care was designed to be "child centered,"

that is, focused on recognizing the psychological as well as the instrumental needs of the young children in their care. In contrast to the frequent placement changes sometimes seen in foster care in the United States, there were very few moves within BEIP foster care. Several of the foster parents ultimately adopted the children they cared for, despite the fact that they would then no longer receive a salary for caring for that child. Foster parents were encouraged by project social workers to accept their foster children as members of the family and to become the "psychological parents" of the children for whom they cared.

The social workers were supported throughout the project by clinicians in the United States who provided weekly phone or video consultations. The consultants also visited the study center quarterly to provide in-person consultation, visit foster homes, and discuss issues that had arisen in the care of this challenging group of children. The emphasis was on developing attachment relationships between foster parents and children, facilitating language development in children, and providing foster parents with techniques for managing difficult child behavior (see Nelson et al., 2007, Supporting Online Material, for further information about the intervention).

Measures

Attachment. The quality of children's attachment to their caregivers was assessed using Ainsworth's SSP (Ainsworth et al., 1978). Community children were seen with their mothers, foster children with their foster mothers, and institutionalized children were seen with their "favorite" caregivers, as identified by staff. If the child did not have an identified favorite, they were seen with a caregiver who worked with them regularly and knew them well.

Coders, who were native Romanians, were trained to reliability in the MacArthur Preschool System with W. Whelan (Cassidy & Marvin, with the MacArthur Working Group, 1992). All procedures were coded by a primary coder who was blind to the children's group status. In addition, 120 (75%) of the procedures were double-coded to reliability; on the five-way (secure, avoidant, ambivalent, disorganized-controlling, and insecure-other) classification, kappa = 0.81 (95% CI = 0.73, 0.89). Percent agreement was 87.7%. For secure versus not secure coding, kappa = 0.83 (95% CI = 0.73, 0.93), percent agreement = 91.7%. For organized (secure, avoidant, and ambivalent) versus atypical (disorganized, controlling, and insecure-other) classifications, kappa = 0.93 (95% CI = 0.85, 1.01), percent agreement = 97.5%. Disagreements were resolved by conferencing.

In keeping with the MacArthur coding system, categories coded included secure (B), avoidant (A), ambivalent-dependent (C), disorganized-controlling (D), and insecure-other (I-O). Although the underlying strategy for obtaining comfort and reassurance from the attachment figure in times of distress remains the same as that seen in infancy, different behaviors are evident in preschool children. For example, secure attachment involves demonstrating a positive, engaged and open style of verbal and nonverbal interaction but less proximity seeking than in infancy. Children whose attachment is classified as avoidant have reduced involvement with the caregiver and do not seek contact when distressed. In addition, they say little to the caregiver, particularly about feelings, and they remain affectively neutral. Children whose attachment is ambivalent-dependent display passivity, helplessness, immaturity, or petulance and resistance in their interactions with the caregiver. Some preschool children whose attachment is classified as disorganized display behaviors similar to toddlers classified as disorganized (see Main & Solomon, 1990), but others exhibit efforts to control the behavior of the caregiver, particularly following the stressful separation episodes of the SSP. Such behavior tends to follow one of two patterns: controlling-caregiving or controlling-punitive (Cassidy & Marvin, with the MacArthur Working Group, 1992). Because disorganized and controlling behavior are conceptually linked, the classification is called disorganized-controlling. Finally, Marvin and his colleagues (Cassidy & Marvin, with the MacArthur Working Group, 1992) identified an ''insecure-other'' classification to describe children who did not fit into the traditionally insecure categories. This classification was prevalent in previous studies of formerly institutionalized children (Marcovitch et al., 1997; O'Connor et al., 2003). Children who are classified as insecure-other are clearly not secure, but they also do not fit into one of the insecure categories described earlier. For example, some children classified as insecure-other display a fearful, ''compulsive-compliant'' pattern; others are severely emotionally dysregulated in the context of their caregiver. Still others exhibit both avoidant and resistant behaviors in their interactions with their caregivers. In other words, such children have not evolved a reliable strategy for managing their distress by seeking and receiving comfort and reassurance from their caregivers. Although behavior in interaction with their caregivers may vary, the underlying attachment representation for children who are categorized controlling or insecure-other, may be characterized by ''themes of fear, confusion, chaos, and disorganization'' (Teti, 1999, p. 230).

In addition to assigning a best fitting classification of attachment, coders also assigned a continuous rating of security, using a scale from 1 to 9, with 1 = *no security evident* to 9 = *most secure* (Cassidy & Marvin, with the MacArthur Working Group, 1992). Reliability for this coding was excellent ($r = .87$).

Cognitive development. The Bayley Scales of Infant Development II (BSID–II; Bayley, 1993) were used to assess developmental status. The Mental Development Index (MDI), a scaled score, ranged from 50 to 150. Children who obtained scaled scores below 50 were assigned a numeric MDI score of 49. Raw scores were assigned an age equivalent score to enable analyses when scaled scores < 50 were obtained (Lindsey & Brouwers, 1999). DQs were computed for each child (i.e., [age equivalent score/chronological age] × 100).

Quality of caregiving. The Observational Record of the Caregiving Environment (National Institute of Child Health and Human Development Early Child Care Research Network, 1996, 1997) was adapted for use in assessing the quality of caregiving for a given child in his or her environment (see Zeanah et al., 2005, for an in-depth description of this measure). Children were videotaped in their ''home'' environment (i.e., CAUG: institution; FCG: foster home; NIG: family home) for 1½ hr with their favorite caregiver. Coders watched the videotape and coded qualitative items (e.g., sensitivity, intrusiveness) on a scale that ranged from 1 = *not at all characteristic* to 4 = *highly characteristic.*

A quality-of-caregiving score was determined by calculating the mean of the scores for sensitivity, stimulation of development, positive regard for child, flat affect (reversed), and detachment (reversed). Possible quality-of-caregiving scores ranged from 1 to 4. Scale reliability was acceptable (Cronbach's $\alpha = .82$).

Consent

Following approvals by the Institutional Review Boards of the three principal investigators (Zeanah, Nelson, and Fox) and by the local Commissions on Child Protection in Bucharest, the study began in collaboration with the Institute of Maternal and Child Health of the Romanian Ministry of Health. Consent was signed by the Commissioner for Child Protection for each child participant living in his or her sector of Bucharest, as dictated by Romanian law. Further assent for each procedure was obtained from each caregiver who accompanied the child to the visit.

Ethical issues involving this vulnerable population have been discussed in detail elsewhere (Millum & Emanuel, 2007; Nelson et al., 2007; Wassenaar, 2006; Zeanah et al., 2006).

Results

Overall distribution of attachment classifications, organization, and security, first, are presented by group. Then we compare security ratings for the groups. We then examine the important question of whether there is a critical age after which placement in foster care is less likely to result in an organized or secure attachment relationship. Finally, we examine whether specific factors such as gender, quality of caregiving, or cognitive skills are useful for predicting organization

Table 2
Distribution of Strange Situation Procedure Classifications

Strange Situation procedure classification	Care as usual (%) (n = 57)	Foster care (%) (n = 61)	Never institutionalized (%) (n = 51)
Secure (B)	10 (17.5)	30 (49.2)	33 (64.7)
Avoidant (A)	14 (24.6)	12 (19.7)	6 (11.8)
Ambivalent (C)	7 (12.3)	5 (8.2)	7 (13.7)
Disorganized-controlling (D)	3 (5.3)	8 (13.1)	5 (9.8)
Insecure-other (I-O)	23 (40.4)	6 (9.8)	0
Organized (A, B, C)	31 (54.4)	47 (77.0)	46 (90.2)
Atypical (D-controlling, I-O)	26 (45.6)	14 (23.0)	5 (9.8)

or security in young children previously institutionalized.

SSP Classifications

The frequency distributions of SSP classifications are shown in Table 2. Differences were most apparent at the extremes of the classifications. Thus, only 17.5% of the CAUG but 49.5% of the FCG were securely attached. Further, 40% of the CAUG but only 13.1% of the FCG were classified as insecure-other. The distribution of the classifications across the three groups differed significantly, $\chi^2(8) = 48.30$, $p < .001$. Comparison of the CAUG and FCG showed a significant difference, $\chi^2(4) = 22.62$, $p < .001$, but no difference was found between FCG and the NIG, $\chi^2(4) = 8.34$, $p = .08$. No significant differences were found between males and females in overall distribution of attachment classifications, nor were gender differences noted in the distributions of any of the individual groups. Ethnicity also was unrelated to any of the attachment measures.

Organization of attachment was dichotomized organized (A, B, and C) and atypical (D-controlling and I-O) as shown in Table 2. Significant differences were found among the three groups, $\chi^2(2) = 18.33$, $p < .001$, and between the CAUG and FCG, $\chi^2(1) = 6.75$, $p < .01$, but not between the FCG and the NIG, $\chi^2(1) = 3.41$, $p = .065$. Differences were noted between males and females in organized versus atypical status for the FCG only, $\chi^2(1) = 4.97$, $p < .05$, with FCG girls more likely to be organized than FCG boys.

In an even more stringent test of the intervention, we compared the frequency of secure (B) versus not secure (all others). Significant differences were found among the three, $\chi^2(2) = 25.79$, $p < .001$, and between CAUG and FCG, $\chi^2(1) = 13.16$, $p < .001$, but not between the FCG and the NIG, $\chi^2(1) = 2.72$, $p = .099$. Gender differences were found within the FCG, $\chi^2(1) = 3.67$, $p = .055$, and the NIG, $\chi^2(1) = 4.29$, $p = .038$; girls were more often secure than boys within this group.

Security Ratings

Coders assigned security ratings ranging from 1 to 9 for each procedure. Table 3 shows the average security rating for each group overall and by gender. Notably, even among dyads classified as secure in the CAUG, security ratings were lower than those of either the FCG or the NIG. Main effects of group, $F(2, 169) = 17.10$, $p < .001$, and of secure versus insecure, $F(1, 169) = 386.37$, $p < .001$, were significant. This pattern was additive across groups, $F(2, 169) = 0.043$, $p = .958$. Security scores were highest among the NIG, next highest among the FCG, and lowest in the CAUG. A similar pattern was present for the organized versus atypical analyses. There was no association of these scores with gender or ethnicity.

Effects of Age at Placement on Organization and Security

To investigate the effect of age at placement into foster care on organization and security, FCG children were grouped by dichotomous age at

Table 3
Security Rating by Group

	Care as usual (%) (n = 57)	Foster care (%) (n = 61)	Never institutionalized (%) (n = 51)
Security rating	3.13 (1.33)	4.61 (1.64)	5.49 (1.52)
Male	3.13 (1.39)	4.29 (1.59)	5.09 (1.65)
Female	3.13 (1.40)	4.96 (1.64)	5.83 (1.34)

Note. Security ratings: 1 = *no security evident*, 9 = *most secure.*

Table 4
Organized Versus Atypical by Placement Age Group

Age cutoff (months)	Percent organized (SSP)			
	Younger	Older	$\chi^2(1)$	*p* Value
18	100	70.2	5.05	.025
20	100	67.4	7.22	.007
22	100	63.2	10.57	.001
24	96.6	58.1	12.41	.000
26	90.9	59.3	8.32	.004
28	85.0	60.0	4.66	.031

Note. SSP = Strange Situation procedure.

Table 5
Secure Versus Insecure by Placement Age Group

Age cutoff (months)	Percent secure (SSP)			
	Younger	Older	$\chi^2(1)$	*p* value
18	53.8	46.8		*ns*
20	58.8	44.2		*ns*
22	63.6	39.5	3.26	.071
24	69.0	29.0	9.57	.002
26	66.7	25.9	9.87	.002
28	60.0	25.0	6.54	.011

Note. SSP = Strange Situation procedure.

placement in foster care (younger than cutoff vs. older than cutoff) for placement cutoffs of 18, 20, 22, 24, 26, and 28 months and then compared by organized versus atypical status and by secure versus insecure status. Tables 4 and 5 show significant differences between organized versus atypical status for children placed earlier when compared to those placed later for all age cutoffs. For secure versus insecure status, however, a deflection point was evident between 22 and 24 months, suggesting that children placed before 24 months had a better response to the intervention of foster care.

Predicting Attachment Organization and Security

Multiple logistic regression was used to determine whether a child had an organized attachment (as opposed to atypical [disorganized or insecure-other] classification) at 42 months of age. Predictors included gender, quality of caregiving, *M* (*SD*): CAUG: 2.54 (0.58); FCG: 2.78 (0.57); NIG: 2.73 (0.57); FCG > IG, and cognitive development (Nelson et al., 2007; see Table 6) as predictors. Logistic regression analyses were conducted for the CAUG, FCG, and NIG separately. For the CAUG, neither caregiving quality nor gender significantly predicted attachment organization, but cognitive development did (Wald $\chi^2 = 5.54$, $p = .019$, $df = 1$). For the children in the CAUG, an increase of 1 unit in DQ at 42 months of age was associated with an increase in the odds of a child receiving care as usual having an organized attachment by a factor of 1.072 (95% CI = 1.012, 1.135). Similar logistic regression analyses performed on the never-institutionalized group and the FCG showed no significant associations between the odds of a child developing an organized attachment with his or her caregiver based on gender, cognitive development, or quality of caregiving. However, when length of time in foster care was added to the logistic regression for the FCG, after controlling for the effect of the other factors, it was the sole significant factor (Wald $\chi^2 = 4.94$, $p = .026$, $df = 1$). An increase of 1 month in length of time in foster care was associated with an increase in the odds of a child in the FCG having an organized attachment by a factor of 1.273 (95% CI = 1.029, 1.574). Length of time in foster care was examined for the FCG only.

Similar analyses were conducted, using gender, quality of caregiving, and cognitive development as predictors to determine whether a child had a secure attachment (as opposed to an insecure attachment classification) at 42 months of age. Logistic regression analyses again were conducted for the CAUG, FCG, and NIG separately. For the

Table 6
Developmental Quotient by Organized Versus Atypical and by Secure Versus Insecure Status

	Care as usual group (%) (*n* = 56)	Foster care group (%) (*n* = 61)	Never-institutionalized group (%) (*n* = 51)	
Developmental quotient	76.90 (13.31)	85.49 (14.23)	103.30 (11.85)	NIG > FCG > CAUG
Organized	81.36 (10.30)	87.97 (13.11)	104.50 (11.49)	Organized > atypical
Atypical	71.36 (14.68)	77.32 (15.18)	92.51 (10.38)	
Secure	77.40 (10.66)	91.03 (11.29)	107.48 (7.50)	Secure > insecure
Insecure	76.79 (13.92)	80.30 (14.89)	95.88 (14.54)	

CAUG, neither caregiving quality, gender, nor cognitive development was associated with secure versus insecure status. However, for the FCG and the NIG, cognitive development at 42 months of age was associated with an increase in the odds of a child having a secure attachment (FCG: Wald $\chi^2 = 5.022$, $p = .022$, $df = 1$; NIG: Wald $\chi^2 = 7.247$, $p = .007$, $df = 1$). An increase of 1 unit in DQ was associated with an increase in the odds of a child in the FCG having a secure attachment by a factor of 1.056 (95% CI = 1.008, 1.106). For children in the NIG, a 1-unit increase in DQ was associated with an increase in the odds of a child in that group having a secure attachment by a factor of 1.144 (95% CI = 1.037, 1.262). When length of time in foster care was added to the logistic regression for the FCG, cognitive development became marginally significant (Wald $\chi^2 = 3.71$, $p = .054$, $df = 1$) but the other factors were not associated with increased odds of secure attachment.

Discussion

This study reports attachment results from the first ever randomized trial of foster care as an intervention for young children who had been abandoned and placed in institutions. We had earlier reported that in this sample, at a mean age of 21 months, institutional care was associated with profound disturbances of attachment, as reflected in part by 65% of the children classified as disorganized and another 13% who showed so little attachment behavior that they were designated "unclassified" in the SSP (Zeanah et al., 2005). Following placement in care for 12–36 months ($M = 19.12$ months, $SD = 6.80$ months), children in foster care made significant gains compared to children who remained in institutions. This was reflected in significantly more of them having secure attachment classifications and also having higher ratings of security. Further, significantly fewer of them had atypical (i.e., disorganized-controlling or insecure-other) classifications. Because we used intent-to-treat analyses, the findings we report are likely conservative estimates of intervention effects.

These findings indicate that young children placed into foster care after early institutional rearing may experience significant recovery with regard to attachment. Furthermore, because of the randomized design, we can conclude that the placement in families was causally related to improvement in the children's attachment status. This is one of several studies that have shown that changing caregiving environments changes children's attachments (Cicchetti et al., 2006; Dozier et al., 2007; Fisher & Kim, 2007; Heinicke et al., 1999; Klein Velderman et al., 2006; Toth et al., 2002; van den Boom, 1994).

The magnitude of these results is notable. For example, the 49% of children classified securely attached in the FCG is greater or equal to what has been reported in two studies of children adopted internationally out of Romanian institutions. Marcovitch et al. (1997) found 30% of 3- to 5-year-olds and O'Connor et al. (2003) found 47% of 4-year-olds were securely attached to their adoptive mothers. Even more striking, only 13% of the FCG were classified as insecure-other, whereas 42% of the Marcovitch et al. (1997) sample and 47% of the O'Connor et al. (2003) sample had this unusual classification. Although adoptive parents in Canada and the United Kingdom are likely to have socioeconomic advantages not available to foster parents in Romania, this may be overshadowed by the absence of cultural transition for the BEIP children compared to those adopted internationally. Because both the Marcovitch and O'Connor samples included children adopted soon after the fall of Ceausescu, the differences in attachment following placement in families may result from more severe conditions of privation than existed 10 years later when the BEIP was conducted. For example, the largest institution for young children in Romania, St. Catherine's Placement Center, known as Bucharest Number One during the Communist era, had 850 children living there in 1989, but only 450 in the fall of 2000.

A second important finding was that age at which children were placed in foster care was powerfully related to recovery of attachment. This was evident in both analyses of organized attachments (secure, avoidant, and ambivalent) and of secure attachment. The younger a child was placed in foster care, the more likely the child would develop an organized attachment at 42 months. For security of attachment, however, children placed before 24 months of age were more likely to have secure attachments at 42 months. One implication of these findings is that at least in the first 3 years of life children retain considerable plasticity for adaptation with regard to attachment. This supports our theoretical notion that attachment reflects experience-expectant neural processes. That is, even following experiences of social and material deprivation, children who are placed in more species typical caregiving environments exhibit a strong disposition to form attachments. On the other hand, another implication of the findings is a decreasing plasticity of attachment with increasing age and are in keeping with Dozier and Bick's (2007) observation that children placed in foster care younger than 12 months were able to develop trusting relationships with new caregivers more quickly than older infants and toddlers (Dozier & Bick, 2007). An important question for future research is the degree to which subsequent experiences can compensate for early adversity and specifically whether the large number of insecure-other attachment classifications predicts subsequent psychopathology or interpersonal difficulties.

Gender seemed to moderate the effects of the intervention, with girls showing more response to the foster care intervention than boys. The pattern of boys in high-risk samples showing greater incidence of disorganized attachment than girls has been noted by Carlson, Cicchetti, Barnett, and Braunwald (1989) and others (David & Lyons-Ruth, 2005; Vondra, Hommerding, & Shaw, 1999). In contrast, most studies examining attachment organization, particularly in lower risk samples, do not show gender differences. It may be that male gender, in the context of markedly compromised environments, poses a risk that it does not in less challenging environments.

On the other hand, we noted that when gender was included in the regression analysis, along with caregiving quality and cognitive development, as factors influencing the likelihood of developing an organized attachment relationship or a secure attachment relationship, it was not significant for any of the groups. In fact, caregiving quality was also not significant. Rather, for the CAUG, greater cognitive development suggested greater likelihood of developing an organized relationship but not of developing a secure one. It is possible that in the context of the institutional setting, children more capable of engaging their caregivers are more likely to develop an organized attachment with their caregivers, although not a secure one. Given that age of placement is confounded with length of time in foster care, it is not unexpected that this factor is an important influence in the development of organized attachment for the FCG.

Individual differences in caregiving quality at 42 months were not related to children's attachment organization. This may be a result of the single, relatively brief observation being insufficient as a measure of caregiving quality, especially considering that a number of children had changed caregiving environments between baseline and 42 months.

The present study is not without limitations. First, because of the practice in Romania of keeping abandoned children in maternity hospitals during the first 6 months of life, none of the children we studied were younger than 6 months of age. This makes evaluating the impact of very early foster care impossible. In addition, comparisons with studies of children adopted out of institutions are more challenging because both the Rutter et al. (2007) and Chisholm (1998) studies found more favorable development in children adopted younger than 6 months. We chose to use the MacArthur approach to code our SSPs and we recognize that whereas several studies have used this methodology, others have used the Preschool Assessment of Attachment (Crittenden, 1992). A comparison of these two methods might be of interest but was beyond the scope of this study. Second, as seen in Figure 1, despite initial random assignment of the institutionalized children to either the CAUG or the FCG, a great deal of movement between and among groups occurred. This was an important ethical constraint, but it made pure group comparisons impossible. We used intent-to-treat analysis and study of the figure indicates that the majority of the movement was in children assigned to CAUG who ended up in families, either adoptive or their own biological families. As a result, we believe that the results we reported are a conservative estimate of the impacts of the intervention. Finally, as noted earlier, one reason we were unable to demonstrate dose–response effects of the intervention may be because the measure of caregiving quality that we used was based on too brief a period of observation or insensitive to important differences.

The unique population of children reared in institutions remains important in our efforts to understand more fully the effects of atypical environments on young children's development and the processes through which they recover from early adversity.

The neurodevelopmental sequelae of early deprivation were examined by testing ($N = 132$) 8- and 9-year-old children who had endured prolonged versus brief institutionalized rearing or rearing in the natal family. Behavioral tasks included measures that permit inferences about underlying neural circuitry. Children raised in institutionalized settings showed neuropsychological deficits on tests of visual memory and attention, as well as visually mediated learning and inhibitory control. Yet, these children performed at developmentally appropriate levels on similar tests where auditory processing was also involved and on tests assessing executive processes such as rule acquisition and planning. These findings suggest that specific aspects of brain-behavioral circuitry may be particularly vulnerable to postnatal experience.

Over the past decade, increased attention has been devoted to the development of children who have spent some or all of their lives in institutional care (Johnson, 2001). The increase in adoption of institutionalized children has heightened concerns about long-term effects of early deprivation. While the deprivation experienced by children in institutional settings is often impossible to accurately quantify, the environments many of these children endure fall below the quality needed to sustain normal physical and behavioral development. As evidence, institutionalized infants and toddlers lose about 1 month of linear growth for every 2–3 months in institutional care (Johnson, 2001), with behavioral development exhibiting similar dramatic delays (Gunnar, 2001). When institutionalized children are placed in families, marked improvements in physical, social, and cognitive functioning are typically observed, yet many of the children maintain persistent behavioral problems (Ames, 1997; Hodges & Tizard, 1989; Rutter, 1998; Verhulst, Althaus, & Versluis-denBieman, 1990, 1992). The developmental difficulties experienced by many of these children raise questions about the effects of early deprivation including factors such as failure to provide adequate nutrition, medical care, stimulation, and the lack of consistent and supportive caregiving relationships. Although early research emphasized the significance of maternal deprivation, Rutter (1981) rightly noted that many other types of stimulation needed for normal development are also deficient in these environments.

The critical questions that emerge from the plight of these children concern which aspects of inadequate stimulation result in cascading developmental effects, which developmental processes are most affected by inadequate early care, and specification

about how the transfer to more normative caregiving can foster growth and recovery following institutionalization. Institutionalized children have experienced highly species atypical deprivation; in many countries the institutional conditions are quite poor: Children may be confined to cots, fed gruel through propped up bottles, lack toys or stimulation, and receive very little linguistic stimulation and/or one-to-one interaction with caregivers (Nelson, 2007; Rutter, 1998). Even in institutions where basic physical needs were met, lack of individualized care and attention remain prominent. At adoption, children generally move into middle- to upper-middle-class families, who are generally highly stable and well educated (Hellerstedt et al., 2008). In short, adoption marks a dramatic termination of deprivation, allowing an examination of the impact of early deprivation and neglect on subsequent development. Adoption into a supportive home can provide a profound natural intervention in the life of a child exposed to significant early adversity (van IJzendoorn, Juffer, & Poelhuis, 2005). As a result, internationally adopted children provide a natural experiment on the impact of different degrees and duration of care on subsequent biobehavioral development. Despite occasional significant adjustment problems of the children, there are very few adoption disruptions for families who adopt internationally (e.g., Brumble, 2007). Furthermore, all studies of children adopted or fostered from institutions have shown that, varying with duration of institutionalization, once out of the institution children begin to show remarkable rebounds in physical and cognitive development (Kreppner et al., 2007; Maclean, 2003). Both the capacity of children to rebound after early institutional care and limitations on recovery imposed by longer periods of institutionalization were recently demonstrated experimentally in a study involving random assignment to high-quality foster care for children who began their lives in Romanian institutions (Nelson et al., 2007). Studying postinstitutionalized (PI) children several years after adoption allows examination of long-term impacts of early experience on children's development.

The present study is specifically motivated by the convergence of behavioral studies of PI children and experimental studies of deprivation on the nonhuman primates (see review by Sanchez & Pollak, 2009). In terms of domains where children do not appear to catch up in the immediate years following adoption, Beckett et al. (2007) reported that children adopted after a prolonged period of institutional care from Romania had significantly lower scholastic attainment scores than those adopted early (before 6 months) either within the United Kingdom or from Romania. A separate research team also concluded that although adopted children showed age-expected development in some domains, adoptions after 12 months of age were associated with problems in school achievement (van IJzendoorn & Juffer, 2006). Another recent report indicated that children residing within Romanian orphanages had poorly developed language abilities (Windsor et al., 2007). One recent study focused specifically on language and cognitive outcomes at 6 and 11 years of age with a large sample of institutionally reared Romanian children adopted into UK families. This study noted few negative effects of deprivation if institutionalization ended before the age of 6 months. Even for the children over 18 months, the presence of even very minimal language skills (the child's ability to imitate speech sounds) at the time of arrival was a strong positive prognostic factor for school-aged cognitive outcomes. Importantly, variations in adoptive parent characteristics were unrelated to differences in the adopted children's cognitive outcomes (Croft et al., 2007). Studies of institutionally reared children yield consistent evidence that early deprivation can have long-term consequences for cognitive functioning and school readiness. Yet, most extant research has employed gross measures of functioning such as checklists, questionnaires, school records, and global developmental quotient (DQ) and intelligence quotient (IQ) tests. While such global measures provide some suggestion of which neural systems may have been affected, they are not specific enough to test hypotheses about the development of neural systems. Our goal was to more directly examine brain–behavior processes in systems believed to underlie children's scholastic performance, such as aspects of attention, inhibitory control, working memory, and learning.

These domains are of interest not only because of the persistent difficulties observed in previously neglected children but because nonhuman primate studies suggest that the prefrontal cortex (PFC) and its associated systems are particularly relevant to understanding cognitive functions and may be especially vulnerable to early experience (e.g., Sanchez, Ladd, & Plotsky, 2001). The PFC develops over a protracted period, well into adolescence (Huttenlocker, 1990; Sowell, Thompson, Holmes, Jernigan, & Toga, 1999). While the timing of development in different regions has not been fully determined, there is evidence that neuronal organization in the dorsolateral prefrontal cortex (DL PFC; Brodman areas 9 and 10) changes dramatically until 5–7 years of age (Blinkov & Glezer, 1968) and slows thereafter. A similar protracted period has been observed for the neurotransmitter systems mediating prefrontal activity. Bourgeois (2000) has plotted the overproduction and pruning of synapses in the rhesus monkey against that of the human, taking into consideration differences in age compression (i.e., the rate at which each species develops), and has reported remarkable similarity across species. Collectively, these data, coupled with the postmortem data, point to a protracted period of PFC development. Presumably, this may allow experience-dependent fine-tuning of attention, learning, emotion, and memory systems (e.g., Black, Jones, Nelson, & Greenough, 1998).

Although it is critical to understand whether and how postnatal deprivation and neglect influence brain development in human children, the human neuroscience evidence is sparse. Two studies conducted by Chugani and colleagues reported that PI children from Romania showed significantly decreased metabolism bilaterally in the orbital frontal gyrus, the infralimbic PFC, the medial temporal structures (amygdala and head of hippocampus), the lateral temporal cortex, and the brain stem as compared to normal adults and children with chronic epilepsy. Diffusion tensor imaging also suggested that the PI children had reduced white matter tracts between the anterior temporal and frontal lobes (Chugani et al., 2001; Eluvathingal et al., 2006). These brain imaging findings are consistent with recent work from the Bucharest Early Intervention Project (BEIP; see Zeanah et al., 2003). For example, this group has reported that children reared in institutions show dramatic reductions in brain activity as revealed by the electroencephalogram and the event-related potential (ERP; see Marshall et al., 2004; Parker, Nelson, & the BEIP Core Group, 2005a, 2005b). Importantly, children placed in high-quality foster care before the age of 2 years show improvement in their electroencephalogram (Marshall, Reeb, Fox, Nelson, & Zeanah, 2008); ERP amplitude also improves with placement in foster care, although it is not time- or sensitive-period dependent (Moulson, Fox, Zeanah, & Nelson, 2009).

The present study sought to determine which domains of cognitive development may be particularly affected by institutional neglect and deprivation using children adopted internationally from orphanages or other institutions. These PI children were (a) adopted over age 12 months, (b) spent at least 75% of their lives prior to adoption in institutional care, and (c) resided in their adoptive families for a minimum of 3 years at the time of testing. We compared these children to two different groups. Our first comparison group consisted of children who were adopted before 8 months predominantly from foster care overseas, having little or no institutional care history. This group helps to control for prenatal factors and heritable factors associated with a child becoming orphaned or abandoned. Our second comparison group consists of nonadopted (NA) children who were reared in their families of origin. As noted by Rutter, Dunn, Plomin, and Simonoff (1997), even when using "normed" neuropsychological evaluations, and especially when using nonstandardized tests, it is critical to include NA children who have grown up in families of similar economic and educational histories to the families of adopted children. Furthermore, for domains that yielded differences between the PI children and both other groups, we examined whether duration of institutional care correlated with the children's performance. Thus, the strategy employed here is to identify as "institutional deprivation effects" those cognitive functions for which the PI group differs from the two comparison groups and, further, whether the duration of institutional care is associated with the outcome within the PI group. Here, we focus on basic cognitive and learning processes that might underlie school-based learning problems.

Method

Participants

The participants were 132 children ages 8 years 0 months to 9 years 11 months. Three groups were examined (see Table 1 for details). A PI group whose selection criteria were adopted at 12 months of age or older (range = 12–78 months, *M* = 23.4 months, *SD* = 12.9) having spent at least 75% of their preadoption lives in institutional care. Over 50% of this group had no experience other than institutional care prior to adoption (*M* = 22.1 months in institutional care, *SD* = 12.4). Children in the PI group were adopted from Asia (*n* = 19), Latin America (*n* = 1), Russia and Eastern Europe (*n* = 27), and Africa (*n* = 1). An early adopted predominantly from foster care (EA) group whose selection criteria were adoption at 8 months or earlier (range = 2–8 months, *M* = 5.2 months, *SD* = 1.7 months) having spent 2 months or less in institutional care. Nearly 83% of this group had spent all of their preadoption lives in foster care overseas.

Table 1
Sample Characteristics

	Postinstitutionalized (*N* = 48)	Early adopted (*N* = 40)	Control (*N* = 44)
Sex (% female)	50	47	55
Age	8 years 4 months (0.5 months)	8 years 4 months (0.5 months)	8 years 5 months (0.5 months)
IQ[a]	105.9 (15.8)	113.7 (16.5)	124.7 (15.7)
Years of parent education	16.3 (2.2)	16.8 (1.6)	16.4 (2.0)
Median family income	75–110K	75–110K	50–75K

[a]Estimated based on Vocabulary and Block Design subtests of the WIS Wechsler Intelligence Scale for Children, 3rd ed. (C–III), or the Leiter International Performance Scale, Revised (Leiter–R) for participants who scored below the normal range on the WISC–III.

Those with institutional experience had been adopted before 3 months of age. Children in the EA group were adopted from Asia (67%) and Latin America (33%). The EA group permitted comparison with children who had experienced loss of birth families and adoption into another culture. Finally, the third group was children born and raised in their birth families in the United States (NA). The children were recruited and tested at two sites, the University of Wisconsin ($n = 58$) and the University of Minnesota ($n = 74$). As shown in Table 1, there were no differences between the three groups in terms of the numbers of boys versus girls, child's age, or parent education. As expected, children in the PI group had lower IQ scores than those children in the two (EA and NA) comparison groups, $F(2, 131) = 16.13$, $p < .001$. On average, adoptive parents had higher family incomes than those from control families, $F(2, 131) = 3.99$, $p = .02$.

Recruitment and Screening

The internationally adopted children were drawn from the Minnesota and the Wisconsin International Adoption Project Registries—registries of families created through international adoption that expressed interest in being contacted about research participation. The NA children were recruited in Wisconsin through fliers and advertisements and in Minnesota from the Institute of Child Development Participant Pool, a registry of children whose parents indicated interest in being contacted about research opportunities in response to a mailing soon after their children were born.

Within 6 months of the present study, the children were all screened to determine if they met the study's group assignment (described earlier) and exclusion criteria. Criteria for group assignment were determined through phone interview and parent questionnaire. Children then participated in an extensive developmental profile, parts of which determined exclusion criteria. Children were excluded if their IQs were below the normal range (< 78), parents reported congenital abnormalities (e.g., Down syndrome or cerebral palsy), and failure on the fetal alcohol syndrome (FAS) screener. We screened for IQ using the Vocabulary and Block Design subtests of the Wechsler Intelligence Scale for Children, 3rd ed. (WISC–III; Weschler, 1998). If children scored below 1 *SD* on either WISC–III subtests, they were subsequently administered the Leiter International Performance Scale, Revised (Roid & Miller, 1997), a nonverbal IQ assessment, to avoid excluding children with normal IQs whose performance might have been affected by the English language demands of the WISC–III. Children were required to pass either the WISC or the Leiter to be included in this study; if they did not reach criterion on both the WISC and Leiter, then they were excluded. Eight children were assessed with the Leiter and of those, 4 (all PI) were excluded because of IQs in the study exclusion range.

To screen for possible FAS, we photographed front and side views of children's faces and analyzed these images using FAS Facial Photographic Analysis Software (Astley, 2003). Children scoring in the moderate range or higher on this screener were excluded and images where coders were uncertain were also reviewed by a pediatric dysmorphologist. Reliability among coders was 100%. Parents of children who failed the FAS screener were contacted and referred for further evaluation. Four children (2 PI, 2 EA) were excluded because of possible FAS. Note that this exclusion criterion only eliminated children with significant facial dysmorphology due to prenatal alcohol exposure. Children with exposures that did not affect facial morphology would not be identified by this method.

In addition to these assessments, children were also administered the Paragraph Comprehension subtest from the Comprehensive Assessment of Spoken Language battery (CASL). The tasks employed in this study were selected because they required only rudimentary language comprehension. Nonetheless, children scoring 2 *SD* below the published norms of this tests were excluded to reduce the possibility that language problems might impair their performance. None of the PI or EA children needed to be excluded because of low CASL scores.

Four PI (8%), 2 EA (3%), and 1 NA (2%) were on stimulant medications for attention problems; these children were tested when parents agreed to withhold medication (e.g., weekends). Across all of the above-mentioned criteria, 1 NA, 4 EA, and 7 PI children were screened but not included in our final sample of 132.

For descriptive purposes, because low birth weight is associated with poorer cognitive functioning, as part of the screening examination parents provided information about the children's birth weight. Parents were asked to check baby books and other records for this information. Parents who were not able to find these records were asked to sign a medical release so that the child's pediatrician could be contacted for this information. Birth weight data were obtained from 97% of the NA, 85% of the EA, and 41% of the PI children. Notably, in cases in which the PI children were abandonned (e.g., typical for Chinese PI children), this information was unknown. Analysis of the birth weight data yielded means in grams for the PI, EA and NA children, respectively, of 2,893 ($SD = 1{,}134$), 2,982 ($SD = 524$), and 3,314 ($SD = 699$), $F(2, 94) = 5.9$, $p < .01$. Hockbergen post hoc tests indicated that both PI and EA groups were lower birth weight, on average, than NA children, although PI and EA birth weight did not differ. Because of the large number of EA children from Asia, we also compared EA and PI children only from that area of the world. The results failed to yield any difference between Asian EA and PI children, $t < .01$, *df* for unequal *ns* = 5.3, *ns*.

Procedure

Neuropsychological functioning was assessed through two well-validated test batteries. One of these, the Cambridge Neuropsychological Test Automated Battery (CANTAB; Cambridge Cognition, Cambridge, United Kingdom), is a computerized series of neuropsychological tests that cover a wide range of cognitive domains. The second battery is the NEPSY Developmental Neuropsychological Assessment (Korkman, Kirk, & Kemp, 1998), a battery developed specifically for use with children. The CANTAB offers several strengths: It has been used extensively with children (Luciana & Nelson, 2002), it has proved sensitive in discriminating various clinical populations from typically developing children, the individual tasks have been studied extensively to confirm their neural correlates (Joyce & Robbins, 1991; Owen, Downes, Sahakian, Polkey, & Robbins, 1990; Owen, Iddon, Summers, & Robbins, 1997; Owen, Morris, Sahakian, Polkey, & Robbins, 1996; Owen, Roberts, Polkey, Sahakian, & Robbins, 1991; Owen, Sahakian, Semple, Polkey, & Robbins, 1995; Saghal et al., 1991; Sahakian et al., 1988), it is computerized for standardized administration, the stimuli cannot be verbalized, and the subtasks require nonverbal responses; thus, performance is not confounded with subjects' verbal skills.

Neuropsychological test. Memory functions were evaluated with three different tests. The first, spatial working memory, tests the child's ability to retain spatial information and to manipulate remembered items in working memory. It is a self-ordered task, which also assesses heuristic strategy. The test begins with a number of colored squares displayed on a computer monitor. By touching the boxes and using a process of elimination, the child should find one blue "token" in each of a number of boxes and use them to fill up an empty column on the right-hand side of the screen. The number of boxes is gradually increased until it is necessary to search a total of eight boxes. The child's score is based upon errors (touching boxes that have already been found to be empty, and revisiting boxes that have already been found to contain a token) as well as response latency, which is age adjusted. Memory for faces assesses the ability to recognize faces after a single exposure. Children are presented 16 pictures of children one at a time for 5 s each, during which children are instructed to remember the faces and identify the sex of each child. Next, the children are presented with pictures of 3 children, 1 of which they previously saw, and they are then asked to identify the picture they saw previously. Thirty min later, this procedure is repeated. The score on this test is based on the sum of correct responses in immediate and delay tasks. Next, we administered a narrative memory test that assesses the ability to retell a story under both free and cued recall conditions. A story is told to the child. Following the story, children are asked to tell the examiner the same story. After the child has recalled as much as they can, the examiner cues details the child did not mention.

Learning processes were evaluated using the paired associates learning test, which assesses visual memory and new learning. Boxes are displayed on the screen and are opened in a randomized order. One or more of them will contain a pattern. The patterns are then displayed in the middle of the screen, one at a time, and the subject must touch the box where the pattern was originally located. If the subject makes an error, the patterns are re-presented to remind the subject of their locations. The difficulty level increases through the test.

Attentional processes were evaluated using five different tasks. The auditory attention and response set test assesses children's ability to maintain selective auditory attention, as well as the child's ability to maintain a complex mental set. In the first part of the task, the child learns to manipulate a red item whenever they hear the word *red*. In the second part of the task, the child then must shift set and respond to red stimuli when hearing the word *yellow*. Match to sample visual search is a matching test, with a speed–accuracy trade-off. Children are shown a complex visual pattern in the middle of a computer screen, and then, after a brief delay, a varying number of similar patterns are shown in a circle of boxes around the edge of the screen. Only one of these boxes matches the pattern in the center of the screen, and the subject must indicate which it is by touching it. Reaction time is measured on the basis of the release of the press pad, which allows for its more accurate measurement. Rapid visual information processing is a test of visual sustained attention. A white box appears in the center of the computer screen, inside which digits appear in a pseudo-random order, at the rate of 100 digits per minute. Children are requested to detect target sequences of digits and to register responses using a press pad. Outcome measures are calculated using signal detection theory. The visual attention test assesses the speed and accuracy with which a child can scan an array and locate targets. Finally, the knock and tap test measures the child's ability to inhibit immediate impulses evoked by visual stimuli that conflict with a verbal direction. The child learns a pattern of motor responses and then must maintain that cognitive set and inhibit the impulse to imitate the examiner's action.

The working memory and knock and tap tasks also involve components of executive functions. We examined two additional aspects of executive function, rule acquisition and manipulation through reversal and planning, here labeled *executive processes*. The intra–extra dimensional shift set (ID/ED) test was used to measure rule acquisition and manipulation through reversal. Two artificial dimensions are used in the test: color-filled shapes and white lines. Simple stimuli are made up of just one of these dimensions, whereas compound stimuli are made up of both, namely, white lines overlying color-filled shapes. Children begin by seeing two simple color-filled shapes and must learn which one is correct by touching it. Feedback teaches the child which stimulus is correct, and after six correct responses, the stimuli and/or rules are changed. These shifts are initially intradimensional (e.g., color-filled shapes remain the only relevant dimension), then later extradimensional (white lines become the only relevant dimension). Children progress through the test by satisfying a set criterion of learning at each stage. In addition, Stockings of Cambridge is a version of the Tower of London spatial planning test, which gives a measure of frontal lobe function (Baker et al., 1996; Owen et al., 1990; Robbins, 1996). Children are shown two displays containing three colored balls. The displays are presented in such a way that they can easily be perceived as stacks of colored balls held in stockings or socks suspended from a beam. The child must use the balls in the lower display to copy the pattern shown in the upper display. The balls may be moved one at a time by touching the required ball, then touching the position to which it should be moved. The time taken to complete the pattern and the number of moves required are taken as measures of the child's planning ability.

Results

Our first set of analyses sought to determine which domains of functioning were either minimally affected by early deprivation or may reflect developmental catch-up following family rearing. Although we could not distinguish between these explanations, we could determine tasks in which our three groups of children performed differently. Omnibus tests revealed group differences in memory functioning, $F_{\text{mult}}(6, 252) = 3.31$, $p = .004$; on tests of attentional functioning, $F_{\text{mult}}(10, 224) = 2.72$, $p = .004$; and on the test of learning, $F(2, 131) = 12.47$, $p = .001$. However, all three groups of children performed similarly on tests of executive processes, $F_{\text{mult}}(4, 254) = 1.20$, *ns*.

Next, we explored those domains (memory, attention, and learning) where multivariate tests suggested group differences to determine which specific tasks discriminated between groups of children. Table 2 shows the descriptive information for

Table 2
Descriptive Data on Domains Exhibiting Significant Group Differences

		Groups			
	Postinstitutionalized	early adopted	Control	Post hoc comparisons	Duration institutional care
Memory tasks					
Spatial working memory[a] (% errors)	52.7 (18.4)	40.9 (19.5)	39.0 (15.7)	PI < Con EA = Con	−.18
Memory for faces[b] (scaled score)	11.1 (3.1)	12.2 (2.8)	12.6 (3.3)	PI < Con EA = Con	−.11
Auditory narrative memory[b] (scaled score)	9.7 (4.1)	10.8 (3.3)	11.4 (3.2)	No significant difference	−.31*
Attention tasks					
Match to sample[a] (% correct)	95.3 (7.3)	96.2 (4.6)	97.4 (3.4)	No significant difference	−.16
Auditory attention[b] (scaled score)	9.2 (1.3)	9.6 (1.4)	9.7 (1.0)	No significant difference	−.06
Rapid visual processing[a] (% correct)	10.5 (6.1)	9.6 (3.9)	8.9 (4.6)	No significant difference	−.04
Visual attention[b] (scaled score)	10.1 (2.3)	12.2 (2.7)	11.7 (2.1)	PI < Con EA = Con	−.33*
Knock and tap[b] (raw score)	28.00 (2.93)	28.69 (1.81)	29.10 (1.05)	PI < Con EA = Con	−.35*
Executive control tasks					
ID/ED[a] (total errors)	41.2 (19.3)	38.3 (23.7)	33.7 (17.6)	No significant difference	.09
Stockings of Cambridge[a] (problems solved)	6.8 (1.8)	7.3 (1.7)	7.0 (1.5)	No significant difference	−.14
Learning task					
Paired associates learning[a] (total errors)	14.6 (13.8)	6.9 (5.9)	6.2 (5.2)	PI < Con EA = Con	−.46**

these tasks, the pattern of post hoc comparison between groups, and the correlations of scores with duration of institutional care. We included sex in our analyses, but in no instance did we find an interaction of sex and group. Where main effects of sex were noted, girls performed better than boys; however, as sex differences did not modify the main effects of group, we do not discuss them further. Information on sex differences is available upon request.

Within the memory domain, the groups performed differently on the spatial working memory test, $F(2, 128) = 7.96$, $p = .001$. Hochberg post hoc tests revealed that PI children performed more poorly than both EA ($p = .008$) and controls ($p = .001$), but that EA children performed similarly to controls (*ns*). The memory for faces test resulted in a marginal group difference, $F(2, 128) = 2.95$, $p = .056$. On this test, PI children scored lower than NA children ($p = .057$), but the EA and NA groups performed similarly. The groups did not differ on auditory memory ability.

In terms of tests of learning, children's performance on the paired associates learning test differed, $F(2, 131) = 12.47$, $p = .001$. PI children performed lower than EA ($p = .003$) and NA ($p < .001$), but EA and NA groups performed similarly (*ns*).

Within the attention domain, groups performed similarly on tests of auditory attention $F(2, 116) = 2.30$, *ns*; match to sample $F(2, 116) = 1.75$, *ns*; and rapid visual processing $F(2, 116) = 1.03$, *ns*. However, the groups differed on the test of visual attention, $F(2, 116) = 8.96$, $p = .001$. Here, PI children performed more poorly than EA ($p = .001$) and controls ($p = .006$), but EA children performed similarly to controls ($p = ns$). There was also a marginal difference on the knock and tap test, $F(2, 116) = 2.92$, $p = .06$. Here, PI children showed more impulsivity than controls ($p = .05$), but there were no other differences between groups.

Discussion

The primary goal of this study was to determine which cognitive processes differentiated children who experienced early institutional deprivation and neglect. PI internationally adopted children differed from both groups of comparison children on tests of visual memory and attention, as well as visually mediated learning and inhibitory control. Yet, these children performed at developmentally appropriate levels on similar tests where auditory processing was also involved. These children also performed well on tests of executive processes involving rule acquisition, manipulation, and planning.

This study was not designed to show precisely which neural circuits are affected by early experience, but the tasks that PI children had difficulty with do provide a useful guide for specifying neuroanatomical substrates that can be more directly examined in future studies. Next, we briefly highlight areas of brain circuitry associated with these tasks. Performance on the memory for faces task reflects an interaction between PFC and stimulus-specific visual cortical association areas that mediate visual working memory. The neurophysiological models of visual working memory developed in the nonhuman primate also holds for humans, based upon event-related functional magnetic resonance imaging (ER-fMRI) studies of facial delay recognition task similar to the one used in the present study (Druzgal & D'Esposito, 2003). Memory tasks such as the one used in the present study involve both visual memory and visual perception. But there is not yet agreement in the field about the neural bases of these processes. Some data suggest that visual memory and visual perception are associated with common neural substrates (Slotnick, 2004), whereas other data suggest that right medial temporal lobe structures are critically involved in retention, but not in the perception, of new faces (Crane & Milner, 2002).

Spatial working memory is a test of the child's ability to retain spatial information and to manipulate remembered items in working memory and also assesses heuristic strategy. The task is considered a sensitive measure of frontal lobe dysfunction based upon studies of nonhuman primates and patients with frontal lobe damage (Owen, Morris, et al., 1996; Owen et al., 1990; Owen et al., 1995; Passingham, 1995). Owen, Evans, and Petrides (1996) used positron emission tomography with magnetic resonance imaging to demonstrate the existence, within the human brain, of two functionally distinct subdivisions of the lateral frontal cortex, which subserve different aspects of spatial working memory. When the spatial working memory task required the organization and execution of a sequence of spatial moves retained in working memory, significant changes in blood flow were observed in ventrolateral frontal cortex (area 47) bilaterally. In contrast, when the task required active monitoring and manipulation of spatial information within working memory, additional activation foci were observed in mid-dorsolateral frontal cortex (areas 46 and 9). Both of these processing stages were required to successfully complete a spatial working memory task (Owen, Evans, et al., 1996). Another study also linked poor performance on the CANTAB spatial working memory task in children to reduced dorsolateral PFC using fMRI (Luna et al., 2002).

It is difficult to link performance on tests of visual attention to distinct neural systems. A recent study used ER-fMRI to measure brain activity as subjects oriented visual attention to an upcoming target. This activation was lateralized to the left hemisphere and reflected a widely distributed network that included (a) structures in parietal and temporal cortices and thalamus usually associated with selective attention; (b) ventral-stream object processing structures in occipital, inferior-temporal, and parahippocampal cortex; and (c) structures in medial- and dorsolateral prefrontal cortex associated with cognitive control (Arrington, Carr, Mayer, & Rao, 2000). In visual attention tasks, subjects will undoubtedly make errors and need to reorient to targets. This same study revealed that brain areas specific to attentional reorientation were right-lateralized and included posterior temporal and inferior parietal regions, as well as prefrontal regions that likely subserve control processes related to inhibition of inappropriate responding (Arrington et al., 2000). In sum, selective visual attention results from distributed brain activity that includes maintenance of the selected object's representation accompanied by suppression of response to ignored objects (Duncan, 1993; Farah, 1990; Phaf, Van der Heijden, & Hudson, 1990), with control of these processes mediated by the medial DL PFC.

Paired associates learning is a stringent test for visual episodic memory and associative learning (Sahakian & Owen, 1992). To perform well, children had to learn the locations of a progressively increasing number of abstract stimuli. Although such a complex behavioral task undoubtedly draws upon widely distributed neural systems, ER-fMRI suggests that successful performance on this type of task relies heavily upon medial temporal lobe connections to the frontal lobe (Aizenstein et al., 2000). Similarly, the knock and tap test cannot be mapped onto discrete circuitry. The test measures the child's ability to inhibit immediate impulses evoked by visual stimuli that conflict with a verbal direction. The child learns a pattern of motor responses and then must maintain that cognitive set and inhibit the impulse to imitate the examiner's action.

Taken together, the present data suggest delayed maturation of select aspects of frontal circuitry, and perhaps reduced functional connectivity of frontal cortex with other neocortical and subcortical regions, plays a key role in scholastic difficulties among children who experienced early institutionalized deprivation and neglect. Indeed, regions of the PFC have long been associated with cognitive processes similar to the ones assessed in this study (Fletcher & Henson, 2001; Owen, Morris, et al., 1996). Studies in nonhuman primates, lesion studies, as well as functional neuroimaging studies in humans, have documented that DLPFC is crucial for maintaining and manipulating information in ways assessed by the tasks used here (Carlson et al., 1998; Fuster, 2000; Goldman-Rakic, 1988; McCarthy et al., 1994; Owen, Evans, et al., 1996; Pierrot-Deseilligny, Rivaud, Gaymard, Muri, & Vermersch, 1995; Sweeney et al., 1996).

The distinction between the performance of PI and EA children suggests (but does not prove) that the ontogenesis of the PFC also includes an extensive postnatal interval. Such an interpretation is consistent with animal studies that reveal, for example, that the thickness of the PFC of the rat brain is not maximal until postnatal day 20, which marks the beginning of the postweaning period (e.g., roughly equivalent to adolescence in humans; Vincent, Khan, & Benes, 1995). Indeed, PI children are often noted to have problems in attention regulation and emotional control, functions presumably influenced by the development of the PFC and its distributed systems (see review by Gunnar, 2001; Shallice et al., 2002). Consistent with this view, Sanchez, Hearn, Do, Rilling, and Herndon (1998) studied rhesus monkeys that were socially deprived between 2 and 12 months of age. These monkeys exhibited cognitive deficits that had also been noted in earlier studies (e.g., Harlow, Harlow, & Suomi, 1971). Sanchez et al.'s MRI studies revealed that the animals' performance on executive function tasks was correlated with decreased neuronal development of prefrontal, medial temporal, and amygdala substrates. Two years later, these monkeys exhibited increased abnormalities in the PFC that were related to the monkeys' performance on learning and working memory tasks (Sanchez et al., 2001). In a separate study, Mathew et al. (2003) reported neuropathological alterations in the PFC of adult macaques with early adverse experience.

There are a number of features of the present study that are important to consider in interpreting these data. First, as described earlier, we excluded children with clear developmental delays or indications of fetal alcohol exposure, which would have artificially exaggerated group performance deficits. By avoiding a situation where a subset of PI children may be experiencing global cognitive delays, we were also able to detect specific patterns of processing deficits. In general, executive function tasks are sensitive to perturbations in children's lives, but effects on these tasks are not specific to certain situations or conditions. If we observed broad or diffuse cognitive deficits in the PI sample, it would not be possible to rule out general attentional, IQ, motivational, motor, or emotional problems as driving children's performance. Yet, in the present study we observed that on a majority of tasks, PI children displayed performance equivalent to their peers, which permits stronger interpretation of those specific areas where deficits emerged. Second, this sample of children represents families who volunteered to participate in research; it may be the case that parents who believed their children were doing particularly well or poorly were more likely to participate. Yet, such sampling issues—if they exist—do not readily explain the pattern of results observed in this study. In addition, our unusual sampling procedures (see Hellerstedt et al., 2008) probably resulted in a group of children that are both diverse and representative.

The study of children reared in atypical situations requires opportunistic approaches that are also fraught with interpretive challenges. Our requirement that the EA group be adopted before 8 months of age and that these children had to spend ≤2 months in institutional care meant that none of the EA children were drawn from Eastern Europe, where adoption processes take more time. Most of the EA children spent most of their preadoptive lives in foster care overseas, an option that did not exist in Eastern Europe between 1990 and 1998, when the children that we tested were adopted. It is likely that prenatal conditions were less optimal for children who end up being placed in orphanage or institutional care overseas than for children born and raised in their families of origin in the United States. In part, the inclusion of a group of children adopted internationally with little or no institutional experience partly addressed this problem. We obtained birth weight data on the majority of both EA and NA children, and found, as might be expected, that the EA children were lower in birth weight than the NA children. Although we were only able to obtain birth weight data on 41% of the PI children, there was no evidence that birth weight differentiated PI from EA children. While we must be cautious in interpretation of these data because we lack evidence on the reliability of the information and are missing substantial data for the PI children, the pattern of data suggests that EA and PI children tended to experience prenatal environments that were impoverished. This tends to clarify, but not resolve, the issue of whether pre- versus postnatal environmental impacts influenced the outcomes we examined.

In terms of the tasks administered to children, it is critical that measurement involves a sufficient level of task difficulty relative to the ability level of participants. In this regard, the specific tasks used in this study are particularly useful. For example, the test of spatial working memory ability and paired associates learning systematically varies the working memory load, which increases the amount of information that needs to be remembered and the number of trials over which it needs to be maintained. The children's pattern of performance across the tasks that we administered did not reveal clear performance deficits on auditory memory and attentional tasks. One possibility is that the deficits observed here are a function of how much information needs to be kept active in working memory over time, and how precisely that information needs to be encoded. At the same time, firm conclusions about neural activity cannot be made based solely on behavioral data. However, these data do underscore the need to employ specific assessments that have been used in imaging and lesion studies and that may allow more fine-grained analysis of the impact of institutional neglect on neurobehavioral development.

Why did the PI children perform better on tasks that relied primarily on auditory, as compared with visual, information? One possibility is that visual development is more vulnerable to postnatal influences. The auditory system starts functioning during the last trimester of gestation (Birnholz & Benaceraff, 1983), whereas the visual system does not start functioning until after birth. Thus, both visual and auditory *functional* development reflect experience-dependent processes; the difference is that auditory experience starts before visual experience, when the brain is at a different point in its development (cf. Kellman & Arterberry, 2006; Saffran, Werker, & Werner, 2006). Sloutsky and colleagues (Robinson & Sloutsky, 2004; Sloutsky & Napolitano, 2003) have demonstrated that young children, unlike adults, exhibit auditory dominance. This may reflect earlier maturation of the auditory system relative to the visual system. It may also be the case that attentional processes more easily engage some stimulus properties. For example, auditory stimuli are serial, transient events that must be perceived quickly whereas visual stimuli are presented episodically for longer periods of time. Thus, attentional systems may allocate more resources to transient relative to stable stimuli. Similarly, Posner, Nissen, and Klein (1976) proposed that attention to visual stimuli must be learned, whereas attention to auditory stimuli is more automatic. Also consistent with the argument that postnatal experience is more likely to influence visual processing, Maurer, Lewis, Brent, and Levin (1999) have demonstrated that the neural circuitry responsible for adults' face expertise is not prespecified but requires early visual experience (see also Nelson, 2001; Pascalis et al., 2005). Because infants have poor visual acuity, their cortices are only exposed to low spatial frequency. Thus, early exposure to visual information sets up the neural architecture for more complex visual processing. These studies have demonstrated that when visual input is delayed by as little as 2 months, permanent visual deficits result (Le Grand, Mondloch, Mauer, & Brent, 1999, 2003; Maurer et al., 1999).

Models of the role of experience in neural development, and the mounting information on molecular processes in neural plasticity, indicate that neural activities (i.e., activity-dependent processes) are critical to brain development (see Fox, Levitt, & Nelson, 2010). This implies that in addition to the stimuli available in the environment, active engagement of the environment may be essential in order for some aspects of cognitive development to occur. While these opportunities abound in typical human rearing environments, institutionalized childrearing may restrict the kinds of dynamic experiences and input necessary for some aspects of neurobehavioral development. It is hoped that the more we understand about the specific aspects of neurodevelopment impacted by early deprivation, the more we can focus on identifying targeted intervention and training experiences that would optimize these children's outcomes.

Effects of Perinatal HIV Infection and Early Institutional Rearing on Physical and Cognitive Development of Children in Ukraine

Natasha A. Dobrova-Krol, Marinus H. van IJzendoorn,
Marian J. Bakermans-Kranenburg, and Femmie Juffer
Centre for Child and Family Studies, Leiden University

To study the effects of perinatal HIV-1 infection and early institutional rearing on the physical and cognitive development of children, 64 Ukrainian uninfected and HIV-infected institutionalized and family-reared children were examined (mean age = 50.9 months). Both HIV infection and institutional care were related to delays in physical and cognitive development, with a larger effect of the rearing environment. Family care, even of compromised quality, was found to be more favorable for children's physical and cognitive development than institutional care. The impact of the quality of child care on physical and cognitive development is discussed in light of future interventions.

Early exposure to cumulative adversity may cause enduring neurobiological changes responsible for a range of developmental deficits in different domains (Nelson, 2007). The major sources of childhood adversity are poor health, economic hardship, and compromised rearing environment. The presence of perinatal HIV infection is associated with all three of them: HIV, as a medical condition, has a direct impact on physical and cognitive development of the child; as a psychosocial phenomenon, pediatric HIV infection is usually accompanied by perinatal adversities, poverty, parental substance abuse and illness, and increased risk of child neglect, maltreatment and abandonment (Klunklin & Harrigan, 2002; Steele, Nelson, & Cole, 2007).

Currently, thanks to the advances in treatment, HIV infection has turned into a chronic, subacute condition rather than an acute lethal disease (e.g., De Martino et al., 2000). At the same time, due to parental death or child abandonment, HIV infection has also become a growing reason for child institutionalization (United Nations International Children's Emergency Fund, 2007). As has been repeatedly demonstrated in previous research, institutional care jeopardizes children's optimal development (e.g., Johnson, Browne, & Hamilton-Giachritsis, 2006). Nevertheless, several studies suggest that in some cases of extremely adverse rearing circumstances well-functioning child-care institutions may offer children a better rearing environment than their own dysfunctional families (e.g., Miller et al., 2007). Therefore, the purpose of this study was to examine the separate and combined influences of HIV status and the type of the rearing environment, that is, biological families and child-care institutions, on children's stress regulation, and physical and cognitive development, as reflected by their diurnal cortisol production, linear growth, general intelligence, and social-cognitive intelligence as indicated by theory of mind.

Previous research demonstrates that HIV infection is usually accompanied by lower birth weight and physical growth delays, and may cause inhibition of cortisol production. The growth failure of HIV-infected children is usually caused by HIV replication, with the resulting immune response affecting the metabolism and consequently physical growth. Growth delays can also occur as a result of perinatal and postnatal insults, unrelated to HIV infection, such as prenatal substance exposure, prematurity, and malnutrition prevalent among children born to HIV-infected mothers, and due to the impact of other HIV clinical symptoms, concurrent diseases, and/or treatment toxicity (Bailey,

Kamenga, Nsuami, Nieburg, & St Louis, 1999; European Collaborative Study, 2003). Furthermore, HIV may cause inhibition of the hypothalamic–pituitary–adrenal system functioning due to the direct effect of the virus on adrenal gland, or as a result of concurrent diseases and/or medical treatment (e.g., Marik, Kiminyo, & Zaloga, 2002).

Cognitive deficits in HIV-infected children can be attributed to structural central nervous system abnormalities and progressive encephalopathy caused by HIV, health condition, and stage of the disease progress (see Wachsler-Felder & Golden, 2002, for a review). Developmental delays in HIV-infected children can, however, also be caused by adverse rearing environment (Brown, Lourie, & Pao, 2000). In fact, several studies suggest that adverse rearing environment may have equal or even larger effects on the development of children than the infection itself (Coscia, Christensen, Henry, Wallston, & Radcliffe, 2001; Smith et al., 2006).

An average family provides children with what is referred to as the average expectable environment. Depending on the child's age, it encompasses a range of species-specific elements, such as protective, stable caregiving, and socialization, and opens opportunities for exploration of the world (Bowlby, 1998; Cicchetti & Valentino, 2006; Hartmann, 1958). The provision of the average expectable environment is an important prerequisite for children's normal development. For children reared in HIV-impacted families, poverty, parental substance abuse, and serious illness are compromising factors falling outside the range of the average rearing environment and leading to adverse developmental outcomes (e.g., Blanchette, Smith, King, Fernandes-Penney, & Read, 2002; De Bellis, 2005; Fishkin et al., 2000; Gottlieb & Blair, 2004).

As to institutional rearing, it clearly falls outside the range of the average expectable environment due to structural neglect that is embedded in the organization and functioning of child-care institutions (van IJzendoorn, 2008): Its regimented nature, high child-to-caregiver ratio, multiple shifts, and frequent change of caregivers almost inevitably deprive children of continuous and reciprocal interactions with stable caregivers, necessary to respond to their developmental needs. Compromised family rearing environment as well as institutional care can lead to physical growth delays (Skuse, Reilly, & Wolke, 1994; van IJzendoorn, Bakermans-Kranenburg, & Juffer, 2007), stress dysregulation (Gunnar & Vazquez, 2006), lower IQ (Nobel, McCandliss, & Farah, 2007; van IJzendoorn, Luijk, & Juffer, 2008), and delayed false belief understanding (Cicchetti, Rogosch, Maughan, Toth, & Bruce, 2003; Pears & Fisher, 2005; Tarullo, Bruce, & Gunnar, 2007; Yagmurlu, Berument, & Celimli, 2005).

The link between compromised rearing environment and developmental deficits may operate through child–caregiver interactions. Studies suggest that even in the condition of structural institutional neglect the quality of caregiving plays a leading role in the children's development. Thus, Smyke et al. (2007) found that for institution-reared children, the caregiving quality was related to three of six developmental outcomes, including cognitive development. Based on adoptive parents' retrospective reports on the standards of institutional care, Castle et al. (1999) established that individualized care in institutions had the strongest positive effect on adoptees' IQ. Intervention studies also support the importance of child–caregiver relationships, demonstrating that even a modest increase of visual, tactile, and auditory interaction between a child and a caregiver (Hakimi-Manesh, Mojdchi, & Tashakkori, 1984), or some extra untutored human care (Hunt, Mohandessi, Ghodssi, & Akiyama, 1976) results in improved physical and mental development of institution-reared children (for a review and meta-analysis of interventions with institutionalized children, see Bakermans-Kranenburg, van IJzendoorn, & Juffer, 2008).

Physical surroundings represent another aspect of the rearing environment influencing child development (directly and via caregivers; see Evans, 2006, for a review). Morison, Ames, and Chisholm (1995) showed that developmental delays in children with early institutional experience were less severe in the presence of toys and worse when children were dirty or soiled while in institutional care. Studies of family-reared children consistently demonstrated that a stimulating and well-organized physical environment allowing free exploration of developmentally adequate objects, toys and books, and language stimulation by caregivers have a positive effect on children's development (e.g., Bradley, 1985). In the current study, we explored how these factors were related to the development of HIV-infected children.

According to Gunnar's (2001) classification, the institutions involved in our study were characterized by the second level of institutional privation, providing adequate nutrition and health care, however, lacking stimulation and stability in child–caregiver relationships (Dobrova-Krol, van IJzendoorn, Bakermans-Kranenburg, Cyr, & Juffer, 2008). This being the case, the question arose whether family care even of compromised quality, as in the case of HIV-impacted families, facilitates the development of HIV-infected children better than institutional care. Or will perhaps institutions that provide fairly clean environments, good medical care, and nutrition, such as those where the present study was conducted, be good enough to facilitate the development of children better than the troubled family environment that HIV-impacted parents provide? And to what extent does the presence of HIV undermine the development of the institution-reared children as compared to their noninfected institution-reared peers? To address these questions, we compared stress regulation, and physical and cognitive development of HIV-infected children with about the same level of immune control over the infection, as reflected by their CD4 T-lymphocyte count (McMichael & Rowland-Jones, 2001), in different rearing environments: families versus institutions. To examine the effect of HIV infection on physical and cognitive development with respect to the type of the rearing environment, we also included family- and institution-reared children without the HIV condition.

We predicted the following: (a) both HIV infection and institutional rearing would lead to stress dysregulation and delayed physical and cognitive development, with an expected larger effect of the rearing environment than of HIV infection, and (b) even compromised family care was expected to be more favorable for the child's development than institutional care, but quality of care within the institution was predicted to be associated with level of cognitive development.

Method

Participants

Participants were 64 children: 13 HIV-infected institution-reared children (mean age = 52.28 months, *SD* = 12.99, range = 34.78–74.16), 16 uninfected institution-reared children (mean age = 48.14 months, *SD* = 9.72, range = 35.11–66.73), 16 HIV-infected family-reared children, (mean age = 52.01 months, *SD* = 14.78, range = 30.18–71.56), and 19 uninfected family-reared children (mean age = 51.44 months, *SD* = 9.77, range = 37.48–67.06). The groups did not differ with respect to age and gender. Data on the background characteristics of children are presented in Table 1. All HIV-infected children were born to seropositive mothers and acquired the infection perinatally. Diagnosis of HIV-1 infection was based on positive viral culture of polymerase chain reaction assay performed after the neonatal period on at least two occasions over 2 months. In the group of uninfected institution-reared children, 5 had perinatal hypoxic neurological conditions (PHNC), whereas there were no cases of PHNC in the three remaining groups. Because previous studies have demonstrated that PHNC are related to altered physical and cognitive development and stress regulation (Ellis et al., 2001; Van Handel, Swaab, De Vries, & Jongmans, 2007), we decided to exclude these children from further analysis. Moreover, one of the HIV-infected family-reared children was excluded because of clear signs of fetal alcohol syndrome not reported in the medical records, resulting in an effective sample of 58 children. The power of the current

Table 1
Descriptive Statistics for Family-Reared Versus Institution-Reared Children

design with two factors (HIV and rearing environment; $N = 58$ children) and an expected large effect size ($f = .40$) was .82; for the multivariate analyses including one covariate (birth weight; see the following) the power was .85.

Institution-reared children. Institution-reared children were recruited from four Children's Homes in Ukraine. The following selection criteria were applied: (a) age between 3 and 6 years old, (b) admission to institutional care within the 1st year of life, (c) no genetic syndromes (e.g., Down syndrome), (d) no evidence of fetal alcohol syndrome in the medical records, and (e) permanent residence in residential care institutions since admission. These selection criteria substantially limited the number of children who could participate in the study. On average, the mean age at admission to institutional care of the uninfected children was 1 month ($SD = 1$, range = 0–3), and they had been living in institutions for 47 months ($SD = 9$, range = 35–65). The mean age at admission to institutional care of the HIV-infected children was also 1 month ($SD = 2$, range = 0–7). One child who was admitted at 7 months of age previously had lived in a hospital and was cared for by the hospital staff. HIV-infected children had been living in institutional care for 51 months on average ($SD = 14$, range = 35–74).

The data on the history of institutionalization showed that in the group of uninfected institution-reared children, 9 were admitted to institutional care because of poverty, 2 because of family disruption, 4 because one or both parents were in prison, and 1 child was an orphan. Since admission to institutional care, 7 of the uninfected children were transferred from one institution to another. For 1 child, information about the number of transfers between institutions was missing. Seven uninfected children remained in occasional contacts with their parents or family members. Among the uninfected institution-reared children, 2 had siblings living in the same institution; the siblings did not participate in our study.

In the group of HIV-infected institution-reared children, 1 child was admitted to institutional care due to poverty, 1 child due to family disruption, and 5 children because one or both parents were in prison; 6 of the HIV-infected institution-reared children were orphans. Five HIV-infected children were once transferred from one child-care institution to another. Three of the HIV-infected children remained in occasional contacts with their biological family members. HIV-infected children had no siblings residing in the same institution.

Family-reared children. Family-reared children were recruited from local Ukrainian kindergartens, schools, and clinics where routine health checks take place. Caregivers of HIV-infected family-reared children were contacted through a nongovernmental organization providing psychosocial support to HIV-infected people in the region. Some of the contacted caregivers refused to participate in the study mainly because several measures (see the following) involved the video-recording of activities at home; some parents refused to participate because of the seemingly complicated procedure of diurnal salivary cortisol sampling, which along with the strict selection criteria limited our sample size. Children were selected according to the following criteria: (a) age between 3 and 6 years old, (b) living in biological families, (c) no genetic syndromes (e.g., Down syndrome), (d) no evidence of fetal alcohol syndrome in the medical records, and (e) no previous history of institutionalization.

All uninfected children were reared in two-parent biological families with at least one employed parent. In two cases, the excessive use of alcohol by fathers was reported. There were no reported cases of criminal records among the parents of uninfected family-reared children. Among HIV-infected family-reared children, 8 were living in two-parent biological families, 4 were reared by single mothers, and 3 by their single biological grandmothers as their parents were unable to take care of the children due to drug abuse. In eight families, at least one parent was using alcohol and/or drugs and in one family both parents were abusing alcohol. In three families, both parents were unemployed. In four families, at least one parent had a criminal record and in one case both parents had criminal records. In two cases, data on criminal records of the fathers were missing. Both uninfected and HIV-infected family-reared children were raised in families with low to middle income, but the monthly income of the HIV-impacted families was significantly lower than of families without HIV, $t(23) = 2.54$, $p < .05$. We tested whether income of the families as a proxy for family socioeconomic status (SES) impacted the outcome measures of the family-reared children, but no significant difference emerged ($.15 < p < .46$).

Procedure

For all children enrolled in the study, informed consent was obtained; for the children in the children's homes from the local department of the Ministry of Health, and for the children in the family-reared group from their parents or primary caregivers. All children were invited for a laboratory assessment procedure. Institution-reared children were accompanied by their "favorite" caregiver, as determined through preliminary informal interviews with children and caregivers. If a favorite caregiver was difficult to identify, the person who spent most of the time with a child and knew him or her best was invited. Family-reared children were accompanied by their primary caregiver. During the laboratory assessment procedure, the children underwent a physical examination (height, weight, and head circumference) and were administered an abbreviated, nonverbal cognitive performance test (Snijders-Oomen Nonverbal Intelligence Test–Revised [SON–R]) and a Theory of Mind (ToM) task. Because of limited time and resources, assessment of the rearing environment was possible only for the HIV-infected children and was conducted during home visits in the case of family-reared children and during visits to childcare institutions for institution-reared children.

Measures

Child HIV-1 health status. Following the assessment procedure, the children's medical records from the regional AIDS center were reviewed in order to obtain the following data: immunological status according to the Centers for Disease Control and Prevention (CDC) classification, cluster of differentiation 4 (CD4) T-lymphocyte counts that reflect the level of immune control over the infection (McMichael & Rowland-Jones, 2001), and duration and type of antiretroviral treatment. CD4 cell counts most proximal to the time of assessment were used (range = 1–3 months). Preliminary analysis revealed no significant difference between the HIV-infected family-reared and institution-reared children on CD4 cell counts, $t(27) = -1.48$, $p = .15$ (see Table 1). Out of 20 children subjected to the treatment, 18 received the same antiretroviral medications. Table 1 shows that 37.5% of family-reared children and 92.3% of institution-reared children were receiving antiretroviral therapy at the time of the assessment; no significant difference between family-reared and institution-reared children was found on duration of antiretroviral treatment $t(15) = -0.57$, $p = .58$. We tested whether the children receiving antiretroviral therapy differed from the nontreated HIV-infected children on all outcome measures, but no significant difference emerged ($.15 < p < .94$).

Physical growth. Data on physical growth were collected from the children's medical records. Measurements of current height, weight, and head circumference of all children were conducted by a trained research assistant during the laboratory visit. For the purposes of the present study, we used birth weight as a marker for prenatal adversities (e.g., Nordstrom-Klee, Delaney-Black, Covington, Ager, & Sokol, 2002; Shankaran et al., 2004). Current height, weight, and head circumference were highly correlated ($rs > .50$), and because faltering of height serves as a good indicator of long term chronic adversities (e.g., Miller, 2005), current height-for-age scores were used as index for physical growth. Height-for-age (HAZ) was calculated with the software program Epi Info™, Version 3.3.2 using the sex-specific 2000 CDC reference database (Dean et al., 2002).

Diurnal salivary cortisol sampling. A six-sample protocol was followed. Saliva samples were collected on a typical day from the institution-reared children by an institutional nurse and from the family-reared children by their parent. The standard saliva collection protocol and assay procedure for determining cortisol concentration in the saliva samples was applied (see for details, Bakermans-Kranenburg, van IJzendoorn, Mesman, Alink, & Juffer, 2008; Dobrova-Krol et al., 2008). Due to the low concentration of saliva within the cotton swabs, 5 HIV-infected and 5 uninfected family-reared children had missing data at one or two of the six sampling points. In these cases, missing cortisol values were generated with log curve estimation analyses using individual sampling times as the independent variable, resulting in 52 children with complete cortisol data. Three HIV-infected children and 1 uninfected family-reared child who had missing data at more than two sampling points as well as 1 HIV-infected family-reared child who refused to cooperate were not included in the analysis involving diurnal cortisol. Another uninfected family-reared child was excluded from the analyses involving diurnal cortisol because he was ill on the day of saliva sampling. Diurnal cortisol scores were log 10-transformed prior to analyses (Azar et al., 2004).

In order to assess the overall secretion of cortisol from awakening until bedtime the "area under the curve with respect to ground" (AUCg) was computed (Pruessner, Kirschbaum, Meinlschmid, & Hellhammer, 2003). Since the AUCg was related to the total time that the children were awake (from awakening till bed time), we corrected the AUCg for children's total time of being awake. In the group of HIV-infected institution-reared children, two outliers on the AUCg were assigned a raw score on the offending variable that differed 1 unit from the next most extreme score in the distribution (Tabachnik & Fidell, 2007).

Cognitive performance. The SON-R was used to assess the children's cognitive performance (Tellegen, Winkel, Wijnberg-Williams, & Laros, 1998). The SON–R is a nonverbal intelligence test for children between 2.5 and 7 years of age that does not require the use of spoken or written language. The test consists of six nonverbal subtests that focus on two different types of abilities: visual-spatial abilities (meaningful pictures) and abstract reasoning (nonmeaningful pictures). Previous research showed that the nonverbal SON–R test is well suited for use with children of ethnic minorities in the Netherlands (Tellegen & Laros, 1993) and in other countries (e.g., Australia: Jenkinson, Roberts, Dennehy, & Tellegen, 1996; China: Zhang, Gong, Sun, & Tian, 1997). In our study, we selected two of the most reliable subtests of the SON–R to assess the children's cognitive performance (Tellegen & Laros, 1993): a visual-spatial performance Patterns subtest and an abstract reasoning Analogies subtest; average internal consistency of the subtests was .76. Convergent validity of the SON–R IQ with the Wechsler Intelligence Scale for Children–Revised Full Scale Intelligence Quotient and Performance Intelligence Quotient was .80, and with the Raven's matrices .74 (Tellegen & Laros, 1993). In our sample, the internal consistency of the used subtests as estimated by Cronbach's alpha was .81. Total cognitive performance score was calculated with the SON–R computer program on the basis of the two subtests.

Theory of Mind. To assess the children's ability to comprehend false belief, we used one of the False Belief tasks: the classic Unexpected-Transfer Task (Baron-Cohen, Leslie, & Frith, 1985). The Unexpected-Transfer Task has a number of advantages when testing children without or with very little productive language skills due to its easily understood storyline supplemented by the use of props, simple vocabulary, and its nonverbal response mode (Baron-Cohen, 1992; Garfield, Peterson, & Perry, 2001). The Unexpected-Transfer Task demonstrated good test–retest reliability, with a kappa of .62 (Hughes et al., 2000). The task was acted out with two dolls, Sally and Anne, each with a different colored basket and a ball, and involved unseen displacement of the object, in which Sally puts a ball in her basket and then leaves the scene. While Sally is away and cannot watch, Anne takes the ball out of Sally's basket and puts it into her box. Sally then returns and the children are asked where they think she will look for her ball. To pass the task children were to answer that Sally will look inside her basket before realizing that her ball is not there, and thus predict an action based on an attributed false belief. The names of the dolls were changed into the culturally appropriate ones.

Rearing environment. The Home Observation for Measurement of the Environment (HOME) inventory was employed to assess the rearing environments of HIV-infected family- and institution-reared children. The Early Childhood HOME inventory is designed to measure the quality and quantity of stimulation and support available to a child in the rearing environment (Bradley et al., 1993). The information needed to score the HOME was obtained during a 45- to 90-min visit to the place where the child lived, during a time when the child and the child's primary caregiver were present and awake. The semistructured interview and observation were conducted with minimal obtrusiveness and allowed observed participants to act normally (Caldwell & Bradley, 2003). The Child Care Early Childhood version of the HOME (CC–EC–HOME) designed for use between 3 and 6 years of age was employed in the study. It contains 58 items clustered into eight subscales: Learning Materials, Language Stimulation, Physical Environment, Caregiver Responsivity, Academic Stimulation, Modeling, Variety of Experience, and Acceptance. The inventory was translated into Russian and the interviewers were trained by the first author. In order to calculate interrater reliabilities, a second observer coded 93% of the CC–EC–HOME observations: Intraclass correlation coefficients for all the subscales scores and the total HOME scores ranged from .73 to .94.

Background characteristics. Univariate analyses of variance (ANOVAs) and chi-square tests showed no significant differences between the four groups on age of the biological mother, child gender, or child age. Differences on the variables related to child background characteristics are presented in Table 1.

Results

Preliminary Analysis

Preliminary analyses did not reveal an association between gender and any of the outcome variables, that is, height at the assessment, diurnal cortisol production, and cognitive performance. Birth weight was significantly related to current height ($p < .01$), marginally related to cognitive performance on SON–R ($p = .06$), and not related to ToM ($p = .11$). We used birth weight as a covariate in our analyses involving height and SON–R. Current age of the child was significantly related only to ToM ($p < .01$) and was taken into account in analyses involving this variable. Mean values and standard deviations of height, diurnal cortisol production, cognitive performance on SON–R, and percentages of children who passed the ToM task are presented in Table 2.

Differences Between Uninfected and HIV-Infected Family- and Institution-Reared Children on Height, Stress Regulation, and Cognitive Performance

Height. Figure 1, based on the height-for-age mean values with standard errors from birth to 48 months of age, shows the development of height of the four groups across infancy and early childhood. Although both groups of HIV-infected children had lower supine length at birth than their uninfected counterparts, this difference was significant only between uninfected family-reared children and HIV-infected institution-reared children ($p < .01$). Figure 1 shows a normal pattern of linear growth of the uninfected family-reared children remaining within 1 *SD* (range = 0.29 to 0.87) of the reference population. For the other three groups, a faltering of linear growth after birth was observed at different periods of their development: the height of the HIV-infected family-reared children remained within 1 *SD* (range = −0.97 to 0.08) of the reference population, the height of the uninfected institution-reared children ranged from −2.09 to −0.75, and the height of the HIV-infected institu-

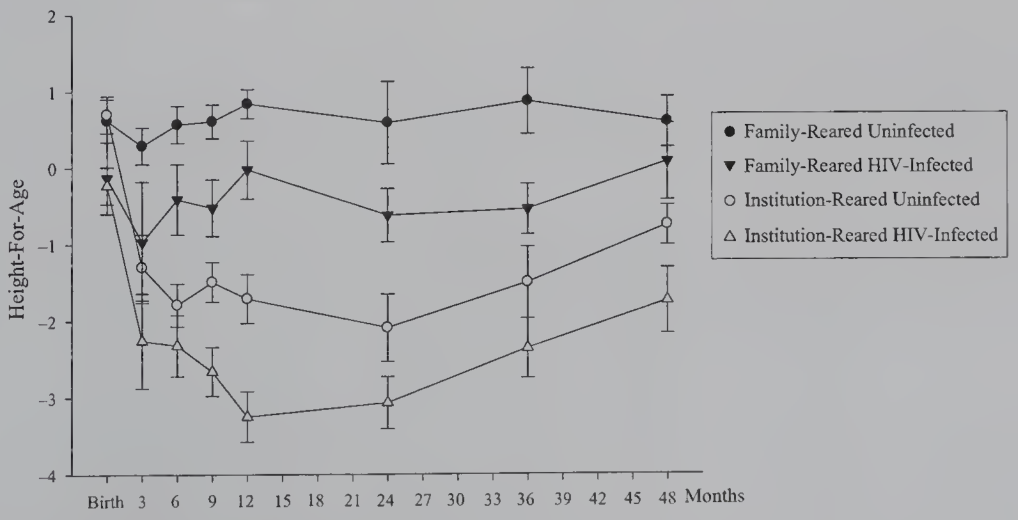

Figure 1. Height-for-age (Z scores, mean, standard error) of uninfected and HIV-infected family- and institution-reared children.
Note. At 36 months, *N* = 47 (family-reared uninfected = 8, family-reared infected = 16, institution-reared uninfected = 10, institution-reared infected = 13); at 48 months, *N* = 35 (family-reared uninfected = 8, family-reared infected = 11, institution-reared uninfected = 7, institution-reared infected = 9).

tion-reared children ranged from −3.25 to −1.74. At the time of the assessment, all four groups had mean height-for-age scores within 2 *SD* from the reference population (see also Table 2).

Stress regulation: Diurnal cortisol production. Figure 2 illustrates diurnal cortisol curves of uninfected and HIV-infected family- and institution-reared children. Table 2 shows the mean values of the total diurnal cortisol production for the four groups of children.

Cognitive performance: SON–R and ToM. As Table 2 shows, cognitive performance on SON–R of the uninfected family-reared children was in the average range (M = 98.94, SD = 19.59), performance of HIV-infected family-reared children was in the borderline deficiency range (M = 79.07, SD = 16.90), and performance of uninfected institution-reared children (M = 69.73, SD = 21.28) and HIV-infected children (M = 64.00, SD = 8.59) fell in the range of mental deficiency according to the SON–R norms (Tellegen et al., 1998). Table 2 presents the percentages of children who passed the ToM task.

Multivariate Analyses

In Table 3, bivariate correlations between the control and outcome variables in the whole sample and as a function of the rearing environment and HIV infection are presented. To assess the difference between the groups as a function of the rearing environment and HIV status, we conducted a multivariate analysis of covariance (MANCOVA) on current height, diurnal cortisol production, and cognitive performance, controlling for birth weight. Significant overall effects were found for rearing environment, $F(3, 44) = 10.23$, $p < .01$, partial $\eta^2 = .41$, and for HIV status, $F(3, 44) = 3.01$, $p = .04$, partial $\eta^2 = .17$. Subsequent ANCOVAs showed main effects for rearing environment and HIV status for both height and cognitive performance and a

*$p < .05$. **$p < .01$.

significant interaction effect for diurnal cortisol production (see Table 2). A priori contrasts revealed that uninfected family-reared children had significantly better scores on current height than both institution-reared groups, and performed significantly better on the SON–R test than all other groups. No significant difference on current height and SON–R between the HIV-infected family-reared children and uninfected institution-reared children was found. HIV-infected institution-reared children had significantly lower current height and SON–R scores than both family-reared groups, but they did not differ significantly from the uninfected institution-reared group (see Table 2). Diurnal production of cortisol was significantly higher in the group of uninfected institution-reared children as compared to uninfected family-reared children and HIV-infected institution-reared children, but uninfected institution-reared children did not differ significantly from HIV-infected family-reared children.

For ToM, chi-square analysis based on the extension of the Fisher's exact test for larger contingency tables and for small sample sizes (Verbeek & Kroonenberg, 1985) demonstrated significant differences between the groups, $\chi^2(3, N = 58) = 8.33$, $p = .04$, with family-reared uninfected children outperforming the other three groups of children. To control for age, we used a median split of the sample on age and compared the children's ToM performance among younger (< 47.86 months) and older (> 47.86 months) children. We found that in the group of younger children the success rate was 43% for uninfected family-reared children and 17% for HIV-infected institution-reared children; none of the HIV-infected family-reared and uninfected institution-reared children passed the task. Among older children the success rate was 73% for uninfected family-reared children, 67% for uninfected institution-reared children, 50% for HIV-infected family-reared children, and 29% for HIV-infected institution-reared children. Separate chi-square analysis conducted to compare the performance of uninfected and HIV-infected family- and institution-reared children in the younger and older groups on ToM demonstrated a significant effect for the younger children, $\chi^2(3, N = 29) = 7.58$, Fisher exact $p = .04$, again with family-reared uninfected children outperforming the other three groups of children, and no effect for the older children, $\chi^2(3, N = 29) = 3.62$, Fisher exact $p = .35$.

Cognitive Development and Environmental Characteristics

To compare the rearing environments of HIV-infected family- and institution-reared children, one-way ANOVAs on HOME subscales and HOME total scores were conducted (see Table 4; HOME scores were not available for the non-HIV-infected participants; see the Method section). To obtain an accurate picture of the magnitude of the differences between the two groups on the various HOME scales, independent of sample size, we also present effect sizes, as reflected by Cohen's *d*. According to Cohen (1988), $d = 0.20$ can be interpreted as a small effect size, $d = 0.50$ as medium, and $d = 0.80$ as large. The rearing environment of the HIV-infected institution-reared children was scored significantly

Table 4
Mean Values, Standard Deviations, and Correlations With Cognitive Performance on SON–R Scores for HOME Scales of HIV-Infected Children as a Function of Rearing Environment

	Total (*N* = 29)		Family-reared children (*N* = 16)		Institution-reared children (*N* = 13)

Acceptance	3.17 (0.89)	.42*	3.63 (0.89)	.15	2.62 (0.51)	.48	13.31**	2.84
Total	41.66 (8.02)	.28	40.81 (10.21)	.30	42.69 (4.21)	.66**	0.39	−0.24

Note. SON–R = Snijders-Oomen Nonverbal Intelligence Test–Revised; HOME = Home Observation for Measurement of the Environment.
**p* < .05. ***p* < .01.

higher than the environment of HIV-infected family-reared children on the Physical Environment subscale, $F(1, 27) = 24.11$, $p < .01$ ($d = -1.94$), and the Variety subscale, $F(1, 27) = 8.23$, $p < .01$ ($d = -1.11$), and significantly lower on the Acceptance subscale, $F(1, 27) = 13.31$, $p < .01$ ($d = 2.84$). No difference was found on the HOME total score, $F(1, 27) = 0.39$, $p = .54$ ($d = -0.24$).

To examine how various aspects of the rearing environment as reflected by the HOME subscales were associated with the cognitive performance of HIV-infected children, we computed the correlations between the HOME subscales and SON–R scores (see Table 4). For the whole group of HIV-infected children higher SON–R scores were related to more Language Stimulation ($r = .54$), and more Acceptance ($r = .42$). For HIV-infected family-reared children higher SON–R scores were related to more Language Stimulation ($r = .50$). For HIV-infected institution-reared children, higher SON–R scores were related to higher total HOME scores ($r = .66$). We did not find any significant relations between the HOME subscales and current height, diurnal cortisol production, and ToM performance.

Discussion

Both HIV infection and institutional care are related to delayed physical growth and poor cognitive performance. The impact of the rearing environment on physical growth and cognitive performance on SON–R was, however, greater than the impact of HIV infection. Family care, even of compromised quality, was found to be more favorable for children's physical growth and cognitive development than institutional care. HIV-infected children reared in disadvantaged families showed better physical and cognitive development not only in comparison to HIV-infected children, but also compared to noninfected relatively healthy children reared in institutions providing good quality physical environments. In families as well as in institutions, better quality of the rearing environment was associated with higher levels of cognitive performance of HIV-infected children. We found elevated diurnal cortisol production in uninfected institution-reared children, and lower levels of diurnal cortisol production in their HIV-infected counterparts. Finally, uninfected children reared in families performed significantly better on the ToM task than all other groups.

The design of the current study provides a unique opportunity to examine how perinatal HIV infection and early rearing environment affect stress regulation, physical growth, and cognitive development of children in an ethnically homogeneous group. Moreover, to control for major differences in the duration and type of institutional care, we assessed children who were admitted to institutional care at 1 month after birth on average and who permanently resided in child-care institutions with about the same level of institutional privation.

Physical Growth

The association between HIV status and lower birth weight and physical growth delays has been well documented in previous studies (e.g., Bailey et al., 1999; European Collaborative Study, 2003), and was replicated in our sample. Archival data showed that delays in physical development of HIV-infected children were evident already at birth and persisted through the course of the child's development as compared to noninfected children raised in similar rearing environments. However, physical growth delays of HIV-infected children reared in families were less substantial in comparison to not only HIV-infected but also uninfected institution-reared children, who received adequate nutritional provision and health care, and whose physical environment was not significantly different from the environment of their family-reared counterparts as revealed by the HOME total score.

Stress Regulation

Our finding of an interaction effect between HIV status and type of care on total diurnal cortisol production indicates that the institutional environment, as a source of repeated daily intermittent stress, may cause an elevation of cortisol production for uninfected children, as also documented in other studies addressing stress regulation of children with institutional experience (e.g., Gunnar, Morison, Chisholm, & Schuder, 2001). In the case of HIV-infected children, it may contribute to a weakened immune system functioning that allows HIV to have a greater inhibiting impact on cortisol production as compared to HIV-infected family-reared children. However, since family- and institution-reared children had similar CD4 T-lymphocyte counts (reflecting the level of immune control over the infection), an alternative and perhaps more plausible explanation is related to antiretroviral treatment that the majority of the HIV-infected institution-reared children and less than half of the family-reared children were receiving, which may also inhibit production of cortisol (e.g., Marik et al., 2002).

Cognitive Performance on SON–R

The cognitive performance of the uninfected family-reared children was in the average range, whereas in the HIV-infected family-reared children it was in the borderline deficiency range, and in both uninfected and HIV-infected institution-reared children it fell in the range of mental deficiency (Tellegen et al., 1998). For institutionalized children, the impact of the infection on cognitive functioning appeared to be not very substantial. In fact, not all aspects of cognitive functioning may be equally affected by the presence of HIV. For example, along with normal performance of HIV-infected children on various measures of IQ, lower levels of performance have been found for executive functioning and processing speed (Koekkoek, De Sonneville, Wolfs, Licht, & Geelen, 2007), visual-spatial and time orientation tests (Tardieu et al., 1995), and motor development (Blanchette et al., 2002). The SON–R test used in our study was not meant to detect impairments in executive functioning.

At the same time, a substantial discrepancy in cognitive performance between family-reared children with and without HIV was observed: It was more than 3 times larger than between institution-reared children with and without HIV. This discrepancy may be attributed to the difference in the rearing circumstances in the HIV-infected and uninfected families. Whereas uninfected children were from relatively normally functioning low-to-middle class families, HIV-infected children were growing up in more problematic family environments. The relatively small difference in cognitive performance of institution-reared children may be explained by the fact that both uninfected and HIV-infected children were raised in mixed groups in the same institutions, and their rearing circumstances were nearly identical. Alternatively, it may reflect a general floor effect in non-neurologically impaired groups.

On average, the institution-reared children were more than 22 IQ points behind the family-reared children, and the gap between HIV-infected institution-reared children and their family-reared counterparts was more than 15 IQ points. Examination of the rearing environments of HIV-infected children living in families and institutions with the HOME inventory revealed no significant differences on the HOME total score between those groups. Interestingly, scores on the individual HOME scales indicate that in comparison to the rearing environment of HIV-impacted families, child-care institutions were providing more toys, books, and games that facilitate learning; the physical environment of the institutions was safer, offered more space, and was perceptually more appealing. Finally, the care arrangements in the institutions provided more variety for the children. However, despite these benefits, HIV-infected institution-reared children showed greater cognitive delay than their family-reared counterparts. Further examination of the individual scales of the HOME inventory revealed that caregivers of the HIV-infected family-reared children were more accepting. Basically, institutional care was offering a better physical environment, whereas families secured more supportive child–caregiver interaction. Our findings suggest that the presence of a primary caregiver, and family care, even of compromised quality, promotes cognitive development of HIV-infected children above institutional care. Importantly, we found that correlations between cognitive performance and different aspects of the rearing environment reflected by the HOME scales were of considerable strength—even if they were not always statistically significant due to small subsample sizes. Also, the overall quality of care within institutions was associated with the cognitive performance of HIV-infected children; however, fairly adequate physical aspects of the rearing environment appeared to be insufficient to facilitate normative cognitive development.

Theory of Mind

More than half of the uninfected family-reared children passed the ToM task assessing the acquisition of false belief understanding, which was more than two times more than in the remaining three groups of children. This difference was especially evident among the younger children. This finding confirms that the average expectable environment facilitates earlier acquisition of ToM. However, although HIV-impacted families secured better child–caregiver interaction than in institutions, it was not sufficiently better to facilitate early ToM development, which requires from caregivers a certain level of sensitivity, fine tuning and mind-mindedness as well as the ability to focus on the child's thoughts and feelings (Fonagy, Gergely, & Target, 2007). In the same vein, another study addressing the development of ToM in family- and institution-reared children demonstrated significantly better results for family-reared children from middle-SES families and failed to demonstrate statistically significant differences between children reared in low SES families and in institutions (Yagmurlu et al., 2005).

Limitations and Future Directions

The major limitation of the current study is its modest sample size that calls for replication of our findings in other countries and institutional settings. However, the power of the study was adequate (> .80) and sufficient to find significant differences of the expected magnitude. The design of the study did not allow for random assignment of children to conditions. Because of the scarce information on perinatal development, we were only able to account for possible effects of birth weight as a proxy for perinatal insults. Besides, children in the four settings may have been systematically different in their genetic makeup, and further studies are needed to extend our understanding of how such genetic differences might contribute to the development of institution-reared children, making them less or more vulnerable to the negative effects of structural neglect (Rutter, 2006). Finally, the group of uninfected family-reared children was different from the other three groups in that these families most likely provided the average expectable environment. On the one hand, conclusions regarding the effects of HIV status on developmental outcomes should remain preliminary until direct comparison with a group of high-risk families without HIV-infected children is made. On the other hand, it does allow assessing differences in the effects of the average expectable environment and institutional care among uninfected children. It should also be noted that income differences between the two types of families were not associated with children's growth parameters, cortisol production, and cognitive development.

Practical Implications

Our study has important practical implications, especially concerning the development and implementation of intervention efforts in child-care institutions, which is the important strength and impact of this study. Our results indicate that it seems to be the quality of child–caregiver relationships and not so much the presence of HIV infection or the quality of the physical environment that contributed to the (delays in) growth and cognitive development of the children in our study. This finding points to the importance of comprehensive but focused intervention efforts in child-care institutions. Renovation of premises and equipping them with toys and learning materials, which has become a popular form of intervention in Eastern Europe, is certainly valuable, but our findings suggest that they may not be sufficient to decrease the gap between the institutional environment and the environment necessary for normative child development.

Of course, family-type of care is the best alternative for institution-reared children. Recent findings of the Bucharest Early Intervention Project (BEIP) in which children were randomly assigned to foster families or institutional care demonstrated that by the age of 4, children in foster care were scoring almost 10 points higher on IQ tests than the children left in the orphanages, and those children who left the orphanages before 2 years of age saw an almost 15-point increase (Nelson et al., 2007). However, much time may pass before in Ukraine, with about 112,000 children under the age of 17 years reared in institutions (State Institute for Family and Youth Development, 2007), emerging alternative care and especially foster care for children with special needs and HIV will substitute institutional care. Unfortunately, HIV-related stigma and fears are still dominating among the general population. Some of the caregivers who participated in our study admitted that they had to conceal their involvement with HIV-infected children from their families. Not surprisingly, children with HIV remain the least preferred candidates for adoption or foster care. Therefore, intervention programs ameliorating the impact of institutionalization are of high importance for those children who are lacking the alternatives of growing up in family care. We believe that in such cases institutions offering good nutritional support and health care, especially important when adherence to the treatment regime is required, may serve at least as a temporary resort for the children. However, changing the structural neglect by enhancing the stability and the quality of the child–caregiver relationship should be a precondition and the major target of the intervention efforts (St. Petersburg-USA Orphanage Research Team, 2008).

Thus, our study fulfills an important pilot function, increasing our knowledge about the physical and cognitive development of an emerging special-needs group of HIV-infected children reared in child-care institutions. Especially now, when the number of HIV-infected children in Ukraine and elsewhere in the world is growing, we hope that the examination of possible risk and protective factors affecting their development will contribute to a better understanding of their developmental processes, and to practical recommendations that ultimately lead to an improvement of their quality of life.

The impact of early physical and sexual abuse (EPA/SA) occurring in the first 5 years of life was investigated in relation to depressive and internalizing symptomatology and diurnal cortisol regulation. In a summer camp context, school-aged maltreated (n = 265) and nonmaltreated (n = 288) children provided morning and late afternoon saliva samples on 5 consecutive days. Child self-report and adult observer reports of child internalizing and depressive symptoms were obtained. Children experiencing EPA/SA and high depressive or internalizing symptoms uniquely exhibited an attenuated diurnal decrease in cortisol, indicative of neuroendocrine dysregulation. These results were specific to EPA/SA rather than later onset physical or sexual abuse or early occurring neglect or emotional maltreatment.

What happens to biological and psychological functioning when there are severe dysfunctions in the early caregiving environment? The study of child maltreatment provides researchers with an excellent opportunity to address this question guided by preclinical research on the impact of early life stress on the development of fear and neuroendocrine dysregulation and by human research on maltreatment, depression, and activity of the hypothalamic–pituitary–adrenocortical (HPA) system. The present report focuses on the impact of physical and sexual abuse (often in combination with neglect) during the first 5 years of life as an example of severe dysfunction of the early caregiving environment.

Among the array of difficulties exhibited by maltreated children, one of the most prevalent and widely documented is an increased risk for internalizing problems and depression in childhood and major depressive disorder in adulthood (Gibb, Wheeler, Alloy, & Abramson, 2001; Kaplow & Widom, 2007; Keiley, Howe, Dodge, Bates, & Pettit, 2001; Kim & Cicchetti, 2006; Manly, Kim, Rogosch, & Cicchetti, 2001; Toth, Manly, & Cicchetti, 1992; Widom, DuMont, & Czaja, 2007). A variety of factors have been posited to mediate the impact of child maltreatment on depression. These include subtype of maltreatment, genetic vulnerability, the quality of children's relationships with their mothers, social support, stressful life events, attributional styles, social competence, self-esteem, and stress hormone activity (Cicchetti & Valentino, 2006). Regarding stress hormones, it has been argued that for those at genetic risk of affective disorder, elevations in stress hormones during episodes of abuse may shape the development of more reactive fear and neuroendocrine systems, and hence increase the risk of developing internalizing disorders (Heim & Nemeroff, 2001).

The animal literature provides support for this hypothesis (Heim, Owen, Plotsky, & Nemeroff, 1997). Chronic elevations in glucocorticoids (cortisol in humans and other primates), produced by the HPA axis, increase the production of fear-mediating neurochemicals in the central nucleus of the amygdala (Makino, Gold, & Schulkin, 1994). In nonhuman primates, individuals' carrying gene

variants associated with risk for depression in abused children (e.g., Caspi et al., 2003) exhibit larger cortisol responses to psychosocial stressors (Barr et al., 2004; Sanchez et al., 2005). Furthermore, a large body of animal studies shows that adverse parental care during early development increases fearful, anxious behavior and shapes increased reactivity in neurobiological systems involved in defensive behaviors and physiological stress reactions (see Gunnar & Quevedo, 2007; Gunnar & Vazquez, 2006, for reviews). In rodents and nonhuman primates, this has been demonstrated through studies of fear behavior and activity of the HPA axis (Levine, 2005; Maestripieri, 1999; Meaney & Szyf, 2005; Sanchez, McCormack, & Maestripieri, in press).

The neurobiological signature of adverse early care has been shown to be highly consistent at the systems and molecular levels to neurobiological findings in the study of adult mood disorder (see Heim, Newport, Mletzko, Miller, & Nemeroff, 2008; Heim, Plotsky, & Nemeroff, 2004). It has been argued that these early effects reflect both the dependence of the very young on maternal care for survival and the rapid development of the brain during the early period of life (Gunnar, 2003; Gunnar & Vazquez, 2006; Heim & Nemeroff, 2001). Thus, these animal studies suggest that inadequate or abusive parenting early in life persistently sensitizes the neurocircuits that are involved in the regulation of stress and emotion, while also suggesting that individuals at genetic risk for depression may be the most susceptible to these early experience effects (Heim & Nemeroff, 2001).

The HPA system has figured prominently in research linking early adverse care to later internalizing and mood disorders for a number of reasons. First, this neuroendocrine system is frequently dysregulated in adults with clinical depression (Holsboer, 2000). Second, both the releasing hormone (corticotropin-releasing hormone [CRH]) and the final hormonal product of this system (cortisol in humans) play critical roles in brain development, affecting neurotrophic factors and regulating gene transcription (Gunnar & Vazquez, 2006). Extremely adverse early care has been shown in animal models to increase cell death in the infant brain (Zhang et al., 2002). During adverse early care, CRH produced in the hippocampus disturbs its normal development (Fenoglio, Brunson, & Baram, 2006), and chronic early stress produces increases in CRH production in the amygdala and a shift in the expression of receptors toward those supporting heightened fear and anxiety (Sanchez, Ladd, & Plotsky, 2001). Finally, heightened fear and activation of the HPA system as a function of early adverse care are then expected to produce an increase in allostatic load over the life course, increasing vulnerability to mood disorders in response to stressors experienced later in development (McEwen, 2003; McEwen & Stellar, 1993).

Models of the impact of early caregiving adversity typically focused on *increased* reactivity of the HPA axis as a likely outcome. However, particularly as the research has been extended to human and nonhuman primates, it has become clear that a more accurate prediction is that the HPA axis will likely exhibit evidence of *dysregulation* and that this dysregulation may involve both hyper- and hypofunctioning (Heim et al., 2004, Heim et al., 2008; McEwen, 2000). Although not yet fully understood, a number of factors have been shown to affect whether elevated or suppressed activity is noted. The HPA axis tends to down-regulate in response to prolonged hyperactivation; thus, in response to chronic stressors first hyper- and later hypoactivity of the axis may be noted (see for review, Miller, Chen, & Zhou, 2007). With regard to basal cortisol, chronic stress and negative emotionality tend to be associated with slight elevations in the late afternoon and evening, but often lower than typical levels in the early morning (e.g., DeSantis et al., 2007; Gunnar & Quevedo, 2007). Thus, whether elevations or suppressions in baseline levels are reported may depend on time of measurement both in terms of time of day and time since the onset of a chronic stressor. Furthermore, in part because of counterregulation within the axis, cortisol measures (baseline or reactivity) may appear normal, even when assessments higher up in the axis (e.g., adrenocorticotropic hormone [ACTH] response to CRH challenge or pharmacological probes of feedback sensitivity) may reveal dysfunction (see, e.g., Heim et al., 2008). Finally, there is some speculation that individuals at genetic risk for antisocial personality disorder will exhibit attenuation or down-regulation of cortisol activity (Susman, 2006), while individuals at risk for depression will exhibit elevations or hyperactivity of the HPA axis following adverse early life conditions (Heim & Nemeroff, 2001; Heim et al., 2004). Overall, predicting that the measures of the HPA system will reflect dysregulation of the axis, rather than predicting that any given measure will be elevated or suppressed, reflects the current status of knowledge in the field. This is especially true in research on young children from vulnerable populations, where researchers are often limited to assessing basal measures of cortisol at only one or a few times during the day.

With these caveats in mind, we review the literature on adverse early caregiving, including maltreatment, and its association with HPA axis dysregulation in humans. Just as not all individuals who experience abuse and neglect as young children grow up to develop clinical depression (Cicchetti & Rogosch, 1996), not all go on to exhibit patterns of HPA axis dysregulation. There is increasing evidence that adults who were abused as children exhibit dysregulation of the HPA axis only or primarily if they have major depression and that adults with major depression in the absence of early child abuse do not show evidence of neuroendocrine dysregulation (Heim et al., 2004; Heim et al., 2008). The results of Heim, Newport, Bonsall, Miller, and Nemeroff (2001) are consistent with studies of children and adolescents with depression. Nonmaltreated children with early onset depression rarely display evidence of regulatory dysfunction of the HPA axis (Feder et al., 2004). Evidence of dysregulation has, however, been noted for depressed children who also were sexually abused and suicidal (Dahl & Ryan, 1996) and for children who were abused and who have chronic posttraumatic stress disorder (Carrion et al., 2002; DeBellis et al., 1999). Similarly, two previous studies of maltreated children have shown that evidence of diurnal dysregulation of the HPA axis (slightly lower morning and slightly elevated afternoon cortisol levels) tends to be observed only in maltreated children who are also suffering from depression (Hart, Gunnar, & Cicchetti, 1996; Kaufman, 1991).

Evidence of dysregulation extends to studies of pharmacological challenge. Specifically, Kaufman et al. (1997) administered a CRH challenge test to a sample of depressed abused, depressed nonabused, and normal control group children. Compared to the depressed nonabused and the normal control group children, the depressed abused children exhibited significantly greater peak, total, and net ACTH secretion post-CRH infusion. Finally, Cicchetti and Rogosch (2001) found that compared to symptomatic nonmaltreated children, maltreated children with clinical-level internalizing problems were distinguished by higher morning, afternoon, and average daily cortisol levels across a 5-day period, suggestive of HPA axis dysregulation.

While dysregulation of the HPA axis appears to be associated with maltreatment for children who are high in internalizing problems or who are clinically depressed, it remains unclear whether this is due to the type, severity, or developmental timing of the maltreatment.

To date, the relevant published studies have either focused on physical or sexual abuse (DeBellis et al., 1999; Heim & Nemeroff, 2001; Kaufman et al., 1997) or have not examined a specific subtype of maltreatment. However, most maltreated children experience multiple types of maltreatment, and the previous studies have not attempted to differentiate among them (Cicchetti & Barnett, 1991; Cicchetti & Rizley, 1981). In particular, abuse and neglect frequently co-occur. Moreover, these maltreatment subtypes have different onsets, occur with varying severities, and can recur (Bolger, Patterson, & Kupersmidt, 1998; English et al., 2005; Manly et al., 2001). In addition, children experience maltreatment during different developmental periods. Thus, maltreatment is a heterogeneous phenomenon, and researchers and clinicians must consider the diversity in the type(s), perpetrator(s), onset, frequency, chronicity, and timing of maltreatment experiences. Even more striking, few such investigations also include a measure of timing, a critical variable in neuroendocrinology (Tarullo & Gunnar, 2006). In particular, inclusion of the temporal dimension is especially important because animal studies have revealed that timing is a crucial factor. Indeed the empirical evidence gleaned from rodent and nonhuman primate investigation indicates that adverse or maltreating (i.e., neglectful and abusive) care early in an animal's life has long-lasting effects. Attempts to translate the animal research on the criticality of timing have utilized a range of time periods (i.e., infancy through adolescence) to specify what constitutes early adverse care. Thus, while there is some evidence that HPA axis dysregulation is associated with maltreatment in the context of depression, little is known about whether the type, timing, or duration of maltreatment is relevant to these findings.

Because, based on the animal literature, dysfunction in the caregiving system early in life is believed to increase the risk of depression in genetically vulnerable individuals (e.g., Heim et al., 2004; Heim et al., 2008), the literature on maltreatment and risk of depression might provide guidance. However, similar problems exist in reviewing the literature on maltreatment and internalizing disorders. Most studies examining maltreatment and depression risk have not examined maltreatment subtypes. Those studies that have examined subtypes often focus on one (e.g., sexual abuse) and not others. Not surprisingly, the results of these studies are inconsistent; some investigations reveal that physically abused and sexually abused children have the greatest likelihood of developing depression, whereas others have shown this is the more likely outcome for neglected and emotionally maltreated children (Cicchetti & Valentino, 2006). Likewise, few prospective studies have examined the interaction between timing and type(s) of maltreatment on depression outcome.

One study that did address all subtypes of maltreatment found that serious neglect experienced during the preschool period was associated with a higher rate of internalizing symptoms (Manly et al., 2001). Another investigation indicated that the experience of harsh physical punishment before age 5 was related to higher teacher ratings of internalizing behaviors in kindergarten children (Keiley et al., 2001). Unfortunately, all types of maltreatment were not addressed in this study. In a study of adults, however, Kaplow, Dodge, Amaya-Jackson, and Saxe (2005) discovered that an earlier age of sexual abuse onset predicted higher levels of anxiety years later. Similarly, Kaplow and Widom (2007) found that individuals whose age of onset of maltreatment (i.e., physical abuse or neglect) was prior to 5 years of age reported higher levels of depressive and anxiety symptoms later in life than did individuals with a later onset of maltreatment (i.e., sexual abuse). These studies suggest that early-occurring maltreatment may be particularly important in the experience of later depression and anxiety. However, limitations in the range of subtypes examined within the studies or the extent to which specific subtypes were adequately represented in the sample preclude definitive conclusions.

In the current investigation, we operationalized early maltreatment as any incident of physical abuse, sexual abuse, neglect, or emotional maltreatment occurring within the first 5 years of life. We chose the infancy, toddler, and preschool periods as our index of early maltreatment for two primary reasons. First, national epidemiological studies of child maltreatment highlight this period as a critical time for the emergence of neglect and abuse (U.S. Department of Health and Human Services, Administration on Children, Youth, and Families, 2000). Second, despite the fact that the neural systems underlying stress reactivity/regulation and internalizing problems undergo a prolonged period of development, components of the limbic system such as the hippocampus, amygdala, and the pathways to the prefrontal cortex from these structures develop rapidly over the first years of life (Thompson & Nelson, 2001).

We also chose to focus on physical and sexual abuse experienced early in the child's life (in the first 5 years). In order to extend the work of Heim (see, e.g., Heim et al., 2008), we utilized prospective reporting of abuse, an earlier age of abuse onset, and evidence for depressive and internalizing symptomatology and cortisol dysregulation occurring earlier in development during the school-age years.

Hypotheses and Research Questions

This study was designed to examine the hypothesis that children who were physically abused, sexually abused, or both prior to age 5 (early physical abuse or sexual abuse [EPA/SA]) and who expressed high depressive and internalizing symptoms would exhibit a more dysregulated pattern of diurnal cortisol activity (less decline, flatter slope) than would other maltreated children (no early physical or sexual abuse [NEPA/SA]) or nonmaltreated comparison (NC) children. Prior to testing this hypothesis, we first examined whether EPA/SA children were at higher risk for developing high depressive or internalizing symptoms than were NEPA/SA or NC children. We also explored the specificity of the finding by contrasting cortisol patterns of the high depressive or internalizing symptom EPA/SA children and subsets of the other maltreated children. First, we examined the contrast with high- and low-symptom children who experienced other forms of maltreatment (neglect, emotional maltreatment) *prior* to age 5. Next, we examined the contrast with high- and low-symptom children whose physical or sexual abuse began after age 5. Finally, we examined whether other parameters of maltreatment (onset, recency, chronicity, diversity, and perpetrators) might be alternative processes that could account for the atypical diurnal regulation for high-symptom EPA/SA children.

Method

Participants

Participants included 553 children aged 7–13 ($M_{age} = 10.02$, $SD = 1.87$) who attended a summer day camp research program designed for school-aged low-income children. The sample included both maltreated children ($n = 265$) and nonmaltreated children ($n = 288$). All of the children were in their 1st year of camp attendance. The children were not in foster care placements and were residing with their biological mothers. Demographic characteristics are presented in Table 1 for the EPA/SA, NEPA/SA, and NC groups. The proportion of boys differed between the NC and both the EPA/SA and NEPA/SA groups, $\chi^2(2) = 17.86$, $p < .001$; thus, gender was controlled in analyses. The groups did not differ in age, race/ethnicity, or in family history of receiving welfare benefits.

Recruitment and Classification Procedures

Parents of all children provided informed consent for their child's participation, as well as for examination of Department of Human Services (DHS) records pertaining to the family. Children in the maltreated group had been identified by the county DHS as having experienced child abuse or neglect, and the sample was representative of the children in families receiving services from the DHS. A recruitment liaison from DHS contacted eligible maltreating families, explained the study, and if parents were interested, released their names to the project team for recruitment. Families were free to choose whether or not to participate. Comprehensive searches of DHS records were completed and maltreatment information was coded utilizing operational criteria from the maltreatment nosology specified in the Maltreatment Classification System (MCS; Barnett, Manly, & Cicchetti, 1993), as discussed below.

Consistent with national demographic characteristics of maltreating families (Third National Incidence Study of Child Abuse and Neglect [NIS-3]; Sedlack & Broadhurst, 1996), the maltreated children were predominantly from low-socioeconomic-status families. Consequently, demographically comparable nonmaltreated children were recruited from families receiving Temporary Assistance for Needy Families. A DHS recruitment liaison contacted eligible nonmaltreating families and described the project, and if interested, parents signed a release for their names to be given to the project for recruitment. DHS record searches were completed for these families to verify the absence of any record of child maltreatment. Trained research assistants also interviewed mothers of children recruited for the nonmaltreatment group to confirm a lack of DHS involvement and prior maltreatment experiences utilizing the Maternal Maltreatment Classification Interview (Cicchetti, Toth, & Manly, 2003). Subsequently, record searches were conducted in the year following camp attendance to verify that all available information had been accessed. Only children from families without any history of documented abuse or neglect were retained in the nonmaltreatment group. In addition, families who had received preventive services through DHS due to concerns over risk for maltreatment were excluded from the sample to reduce the potential for unidentified maltreatment existing within this group.

Classification into maltreatment subgroups was accomplished through use of the MCS (Barnett et al., 1993). The MCS is a reliable and valid method for classifying maltreatment (Bolger et al., 1998; English et al., 2005; Manly, Chicchetti, & Barnett, 1994) that utilizes DHS records detailing investigations and findings involving maltreatment in identified families over time. Rather than relying on official designations and case dispositions, the MCS codes all available information from DHS records, making independent determinations of maltreatment experiences. Based on operational criteria, the MCS designates all of the subtypes of maltreatment children have experienced (i.e., neglect, emotional maltreatment, physical abuse, sexual abuse) and the severity of each type on scales that range from 1 (*least*) to 5 (*most*) severe. Based on documented records, the MCS also determines when in the course of development maltreatment events occurred, providing indices of timing. Events were coded as occurring during five developmental periods, including infancy (0–12 months), toddlerhood (13–36 months), preschool (36–60 months), early school age (ages 5–7), and later school age (ages 8–12). The timing information allows for the determination of whether maltreatment occurred within

Table 1
Demographic Characteristics

	Early physical/ sexual abuse (n = 60)	Maltreated without early abuse (n = 205)	Nonmaltreated (n = 288)
	M (*SD*) or %	*M* (*SD*) or %	*M* (*SD*) or %
Age	9.91 (1.91)	10.02 (1.85)	10.08 (1.89)
Gender (% male)	70.0	58.5	44.4
Race/ethnicity			
African American	50.0	64.9	65.3
Latino	23.3	11.7	17.4
Caucasian	25.0	21.0	14.9
Other	1.7	2.4	2.4
Family history of welfare	96.7	95.0	96.0

each of the developmental periods. The developmental period of *onset* of maltreatment and the *recency* of maltreatment can be determined, and the number of developmental periods of maltreatment serves as an index of *chronicity*. Moreover, the developmental timing of each of the maltreatment subtypes also can be specified.

Coding of the DHS records was conducted by trained research assistants, doctoral students, and clinical psychologists. Coders were required to meet acceptable reliability with criterion standards before coding actual records for the study. Coders demonstrated acceptable reliability (weighted κs with the criterion ranging from .86 to .98). Reliabilities for the presence versus absence of maltreatment subtypes (κs = .90–1.00) and for individual subtypes severities (weighted κs = .75–1.00) also were established.

In terms of the subtypes of maltreatment, *neglect* involves failure to provide for the child's basic physical needs for adequate food, clothing, shelter, and medical treatment. In addition to inadequate attention to physical needs, forms of this subtype include lack of supervision, moral or legal neglect, and education neglect. *Emotional maltreatment* involves extreme thwarting of children's basic emotional needs for psychological safety and security, acceptance and self-esteem, and age-appropriate autonomy. Examples of emotional maltreatment of increasing severity include belittling and ridiculing the child, extreme negativity and hostility, exposure to severe marital violence, abandoning the child, and suicidal or homicidal threats. *Physical abuse* involves the nonaccidental infliction of physical injury on the child (e.g., bruises, welts, burns, choking, broken bones). Injuries range from minor and temporary to permanently disfiguring. Finally, *sexual abuse* involves attempted or actual sexual contact between the child and a family member or person caring for the child for purposes of that person's sexual satisfaction or financial benefit. Events range from exposure to pornography or adult sexual activity, to sexual touching and fondling, to forced intercourse with the child.

Children in the maltreatment group all had histories of abuse, neglect, or both occurring in their families according to DHS records. Among the maltreated children, 79.2% had experienced neglect (*M* neglect severity for those with neglect = 3.42, *SD* = 1.13), 67.8% had experienced emotional maltreatment (*M* severity = 3.44, *SD* = 1.24), 32.6% had experienced physical abuse (*M* severity = 2.56, *SD* = 1.04), and 8.3% had experienced sexual abuse (*M* severity = 2.85, *SD* = 0.94). The majority of children had experienced multiple subtypes of maltreatment. Specifically, 65.2% of the maltreated children had experienced two or more maltreatment subtypes, and 13 of the 15 possible combinations of presence versus absence of each of the four maltreatment subtypes were observed in the sample. On average, the maltreated children had experienced 1.89 (*SD* = 0.78) subtypes of maltreatment. The number of subtypes of maltreatment provides an index of maltreatment *diversity*.

Based on the MCS, we identified a group of children (*n* = 60) who had experienced *early abuse*, that is, physical or sexual abuse or both occurring prior to age 5 in the infancy, toddler, or preschool developmental periods (EPA/SA). In primary analyses, these children were contrasted with the remaining maltreated children (*n* = 205) who had *not* experienced early physical or sexual abuse (NEPA/SA), for example, experienced neglect or emotional maltreatment only or later onset of physical or sexual abuse.

Day Camp Procedures

Children attended a week-long day camp program and participated in research assessments (see Cicchetti & Manly, 1990, for detailed descriptions of camp procedures). Children were transported by bus to the camp each day, with travel time averaging 45 min. At the camp, children were assigned to groups of eight (four maltreatment, four control) same-age and same-sex peers. Each group was led by three trained camp counselors, who were unaware of the maltreatment status of children and the hypotheses of the study. Camp lasted 7 hr/day for 5 days, providing 35 hr of interaction between children and counselors. In addition to the recreational activities, after providing assent, children participated in various research assessments and provided morning and afternoon saliva samples. Trained research assistants, who also were unaware of research hypotheses and maltreatment status, conducted individual research sessions with children, in which questionnaires and other research measures were administered. Clinical consultation and intervention occurred if any concerns over danger to self or others emerged during research sessions. The counselors, who had been trained extensively for 2 weeks prior to the camp, also completed assessment measures on individual children, based on their 35 hr of observations and interactions with children in their respective groups. Counselors were unaware of the research hypotheses and children's maltreatment status.

Day Camp Measures

The camp context allowed for a setting where a consistent collection of saliva samples could occur at uniform times across the camp week. Each day upon arrival to the camp at 9 a.m., trained research assistants obtained saliva samples from each child. Given the approximate 45-min transportation time and the time spent being greeted by camp staff, children had been awake at least 1 hr prior to providing the morning saliva samples, thus avoiding the period of the dynamic cortisol awakening response (cf. Susman et al., 2007). Samples also were obtained each day prior to the children's departure from the camp at 4 p.m.

The children had not consumed food or drink for at least 30 min before each saliva sample was obtained. Samples were collected following the method recommended by Schwartz, Granger, Susman, Gunnar, and Laird (1999). The children were asked to chew Trident® sugarless original flavor gum to stimulate saliva flow and then passively drool although a short drinking straw into a 20-ml plastic vial. The samples were immediately frozen and stored at −40 °C. Each week, the samples were shipped overnight on dry ice for next day delivery to Salimetrics Laboratories (State College, PA) for assay. Cortisol was assayed in duplicate by Salimetrics Inc. using an enzyme immunoassay (Salimetrics Inc.). This assay has a lower limit of sensitivity of 0.007 μg/dl (range up to 1.8 μg/dl), and average intra- and interassay coefficients of variation less than 5.0% and 10.0%, respectively. Units of cortisol are expressed in μg/dl (micrograms per deciliter). Across camp days, the mean morning cortisol level was 0.19 (*SD* = 0.11), and the mean late afternoon level was 0.11 (*SD* = 0.07). As cortisol values were positively skewed and leptokurtotic, logarithmic transformations (log 10) of cortisol values were used for all statistical analyses. Values were averaged across days to yield one morning and one afternoon cortisol measure for each child.

Internalizing and Depressive Symptoms

Children's Depression Inventory (CDI). The CDI is a widely used self-report questionnaire to assess depressive symptomatology in school-age children (Kovacs, 1982, 2004). For each item, children chose from among three option statements, depicting increasing levels of depressive symptoms, in order to characterize their experiences in the past 2 weeks. Kovacs (2004) reports that internal consistency for the total scale has ranged from 0.71 to 0.89, and validity has been well established. In the current investigation, internal consistency was 0.85. A total score of 19 and above has been established as a cutpoint for clinical level depressive symptoms (Kovacs, 2004). In the current sample, 11.4% ($n = 63$) of the children reported clinical-level depressive symptoms.

Teacher Report Form (TRF). Behavioral symptomatology was evaluated at the end of each week by counselors' completion of the TRF (Achenbach, 1991). The TRF is a widely used and validated instrument to assess behavioral disturbance from the perspective of teachers, and the measure was used in the present study because camp counselors are able to observe similar behaviors to that of teachers. The TRF, containing 118 items rated for frequency, assesses two broadband dimensions of child symptomatology, internalizing and externalizing, as well as total behavior problems. In the present investigation, we focus on the internalizing dimension, which includes subscales of withdrawn, somatic problems, and anxiety/depression. Interrater reliability for the internalizing scale was based on average intraclass correlations among pairs of raters. Across the years, reliabilities for internalizing ranged from 0.56 to 0.84 ($M = 0.68$), consistent with the greater difficulty in observers rating internalizing symptoms (Achenbach, 1991). Internal consistency was 0.84. The counselors' scores for each child were averaged to obtain individual child scores for the internalizing dimension. Utilizing the *T* scores for the internalizing scale, a cutpoint of 60T was used to designate the presence or absence of high internalizing symptoms (Achenbach, 1991). In the sample, 9.9% of the participants ($n = 55$) were classified as having high-level internalizing problems.

Summary measure of internalizing. To yield a multi-informant index of children displaying high depressive and internalizing symptomatology, child and counselor measures were combined. Overall, the CDI and TRF internalizing scores were significantly but not strongly correlated, $r = .20$, $p < .001$. Similarly, the high symptom level groups for the CDI and TRF were significantly but weakly associated, $\chi^2(1, N = 553) = 4.48$, $p = .03$. This level of correspondence is consistent with the degree of agreement typically found between different sources of report for child internalizing symptoms. To combine both perspectives, the presence of high symptoms on either the CDI or the TRF was determined and used as an index of high depressive and internalizing symptomatology, resulting in 19.3% of the children being classified as symptomatic.

Results

Plan of Analysis

The analysis was complicated by the complexity of maltreatment subgroup categorization, based on maltreatment subtype and developmental timing of individual subtypes, and concomitant cell sizes, particularly when participants were further classified by the presence of high versus low depressive or internalizing symptoms. We, therefore, pursued a layered approach to these analyses. First, maltreatment parameters of the EPA/SA were examined relative to characteristics of other maltreated children (NEPA/SA) for descriptive purposes. Second, we examined whether the EPA/SA group differed from the NEPA/SA and NC children on depressive and internalizing symptoms, as well as morning and afternoon cortisol levels. Third, we examined main and interaction effects of early abuse and depressive or internalizing symptoms on cortisol levels and change from morning to late afternoon. Gender and age effects also were probed. Fourth, using only the maltreated children, we examined the specificity of EPA/SA: first, relative to *early* neglect or emotional maltreatment without early abuse, and next, relative to *later onset* of physical or sexual abuse at age 5 or older. Finally, other aspects of maltreatment timing, diversity, and perpetrator were considered to determine whether these features of maltreatment influenced cortisol regulation in the context of high symptomatology.

Characteristics of the EPA/SA Group

Within the EPA/SA group, 80% had experienced physical abuse and 28.3% had experienced sexual abuse; 5 children had experienced both maltreatment subtypes. Physical and sexual abuse often occurred in the presence of neglect and emotional maltreatment. In fact, 73.3% of the children in the EPA/SA group had experienced neglect, and 73.3% had also experienced emotional maltreatment. Overall, the EPA/SA group had been exposed to an average of 2.55 subtypes of maltreatment (*SD* = 0.70). The individual subtype severities for children who had experienced respective subtypes did not differ between the EPA/SA and NEPA/SA groups (*ps* = .15 to .77).

Among the maltreated children, 89.8% had experienced some form of maltreatment from their mothers, and this rate did not differ for the EPA/SA (91.7%) versus NEPA/SA children (89.3%) groups, $\chi^2(1, N = 265) = 0.29$, $p = .81$. The rate of fathers as perpetrator also was comparable by group, $\chi^2(1, N = 265) = 0.04$, $p = .88$, 43.3% versus 42.0%. However, the rate of others as perpetrator was higher in the EPA/SA group (58.3%) than the NEPA/SA group (35.1%), $\chi^2(1, N = 265) = 10.39$, $p = .002$.

For the EPA/SA group, the onset of maltreatment had occurred in infancy for 43.3%, in toddlerhood for 25.0%, and in preschool for 31.7% of the early abuse group. Moreover, 63.3% of the children had been maltreated during the toddler period and 93.3% had been maltreated in the preschool period. However, in terms of recency, only 18.4% had been maltreated beyond the preschool period. Chronicity of maltreatment, as indexed by the number of developmental periods of maltreatment, averaged 2.22 developmental periods (*SD* = 0.92).

Group Differences on Depressive and Internalizing Symptoms and Cortisol

Analyses of variance were conducted to contrast children in the EPA/SA, NEPA/SA, and NC groups on CDI and TRF internalizing scores (see Table 2). Results differed depending on whether child self-report or counselor reports were used. For child self-reported symptoms on the CDI, the main effect of group was marginally significant, $F(2, 550) = 2.62$, $p = .07$. In contrast, significant differences for group classification were found for counselor-reported TRF internalizing symptoms, $F(2, 550) = 9.14$, $p < .001$. Tukey post hoc tests indicated that the EPA/SA group had higher internalizing scores than the NEPA/SA and NC children.

As described in the Method section, the presence of high symptoms on the CDI or the TRF was used as an index of high depressive and internalizing symptomatology. Significant group differences were observed on the presence or absence of high symptoms, $\chi^2(2, N = 553) = 11.71$, $p = .003$. Follow-up contrasts indicated that the EPA/SA group (33.3%) had significantly higher rates of symptoms than the NC children (14.9%), $\chi^2(1, N = 348) = 11.34$, $p = .001$, and marginally higher rates than the NEPA/SA children (21.5%), $\chi^2(2, N = 265) = 3.57$, $p = .06$. Finally, the NEPA/SA maltreated children had marginally higher rates of ele-

Table 2

Comparison of Early Physical/Sexual Abuse Classification Groups on Depressive and Internalizing Symptoms and Cortisol

	Early physical/sexual abuse (n = 60)	Maltreated without early abuse (n = 205)	Nonmaltreated (n = 288)
	M (*SD*)	*M* (*SD*)	*M* (*SD*)
CDI total score	10.43 (7.84)	9.32 (7.75)	8.30 (6.70)
TRF internalizing *T* score	51.79 (9.48)$_a$	48.91 (7.99)$_b$	47.29 (7.15)$_b$
	% (*n*)	% (*n*)	% (*n*)
High CDI or TRF	33.3 (20)$_a$	21.5 (44)$_{ab}$	14.9 (43)$_b$
	M (*SD*)	*M* (*SD*)	*M* (*SD*)
Average morning cortisol	−0.82 (0.19)	−0.79 (0.20)	−0.78 (0.18)
Average afternoon cortisol	−1.04 (0.16)	−1.03 (0.17)	−1.03 (0.15)

Note. Groups having the same subscript are not significantly different. Cortisol values are log transformed (log 10). CDI = Children's Depression Inventory; TRF = Teacher's Report Form.

vated symptoms than the nonmaltreated children, $\chi^2(2, N = 493) = 3.52$, $p = .06$. Finally, as shown in Table 2, the groups did not differ on average morning, $F(2, 550) = 1.52$, $p = .22$, or afternoon cortisol levels, $F(2, 550) = 0.07$, $p = .94$.

Diurnal Cortisol Regulation: The Interaction of EPA/SA With Depressive and Internalizing Symptomatology

A 3 (EPA/SA groups) × 2 (depression/internalizing level) × 2 (AM/PM cortisol) repeated measures analysis of covariance (ANCOVA) was conducted, covarying age and gender (see Table 3). In addition to significant gender and age effects, a significant main effect was found for symptom level and a marginally significant main effect was obtained for EPA/SA classification group. However, these main effects were qualified by a significant interaction among group, symptom level, and AM/PM, $F(2, 545) = 6.07$, $p = .002$. Follow-up tests for simple effects were conducted separately within the high and low symptom levels. As shown in Figure 1a, for children who were not high on depressive or internalizing symptoms, no effect of group on diurnal variation in cortisol was obtained, $F(2, 441) = 0.81$, $p = .45$. As shown in Figure 1b, for children with high depressive or internalizing problems, group status was a significant predictor of diurnal cortisol activity, $F(2, 104) = 5.94$, $p = .004$. To further pinpoint the effect for the high-symptom children, we computed the AM to PM decline (AM minus PM) and subjected these scores to an ANCOVA now entering morning cortisol, gender, and age as covariates. The effect of group was significant, $F(2, 101) = 4.27$, $p = .017$. Bonferroni-corrected post hoc comparisons indicated that the EPA/SA group had a significantly lower diurnal decline in cortisol (0.12) than the NEPA/SA group (0.23) and the NC group (0.25). The morning and afternoon scores also were examined separately. Although the group differences were in the expected direction (see Figure 1b), the groups did not differ significantly at either time of day. Thus, the EPA/SA group with high depressive or internalizing symptoms was distinguished by the smaller decrease or attenuated slope of the daytime diurnal rhythm of cortisol, due to slightly but not significantly lower AM and slightly but not significantly higher afternoon levels than the other children.

Table 3

Repeated Measures (Morning and Afternoon Cortisol) Analysis of Covariance for High Depressive or Internalizing Symptoms and Early Physical or Sexual Abuse Classification Groups

Source	*df*	*F*	η^2	*p*

Early Physical/Sexual Abuse × High Symptoms × Time	2	6.07	.022	.002
Error	545			

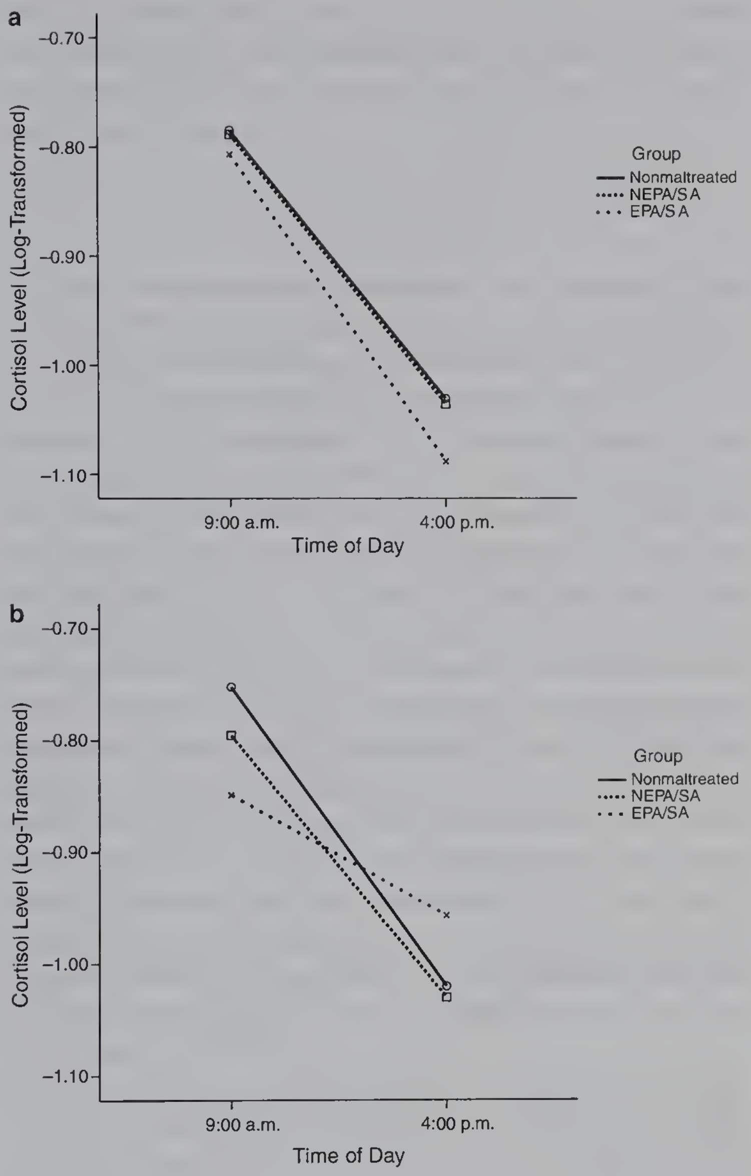

Figure 1. (a) Children with *low* depressive and internalizing symptoms: Diurnal cortisol regulation in early abuse classification groups. (b) Children with high depressive or internalizing symptoms: Diurnal cortisol regulation in early abuse classification groups.

Note. Cortisol values are in μg/dl with log 10 transformation, adjusted for covariates. EPA/SA = early physical or sexual abuse; NEPA/SA = maltreated, but not early physical or sexual abuse.

The effects of the covariates of gender and age on the within subjects diurnal decrease in cortisol are represented in the repeated measures ANCOVA by the respective interactions of the covariates with time. To interpret the effects of the covariates, the difference between morning and afternoon cortisol was computed, and t tests were conducted for gender and age groups (< 10 and ≥ 10). Gender differences were found, $t(551) = 2.83$, $p = .005$, such that girls had a significantly greater cortisol decrease across the day ($M = 0.27$, $SD = 0.17$) than boys ($M = 0.22$, $SD = 0.19$). Although morning cortisol levels did not differ by gender, $t(551) = 0.74$, $p = .46$, afternoon levels did, $t(551) = 2.41$, $p = .02$, with boys having higher cortisol ($M = -1.02$, $SD = 0.16$) than girls ($M = -1.05$, $SD = 0.16$). Interpretation of the covariate effect of age involved a significant effect of age group on diurnal cortisol decrease, $t(551) = 6.12$, $p < .001$, with older children evincing a steeper decrease ($M = 0.29$, $SD = 0.19$) than younger children ($M = 0.19$, $SD = 0.17$). Older children had significantly higher morning cortisol levels than younger children, $t(550.9) = 5.46$, $p < .001$ ($M_{\text{older}} = -0.74$, $SD = 0.20$; $M_{\text{younger}} = -0.83$, $SD = 0.17$). Afternoon cortisol did not differ, $t(551) = 0.56$, $p = .58$.

Because puberty is associated with a rise in basal and reactivity measures of the HPA axis (Adam, 2006; Gunnar, Wewerka, Frenn, Long, & Griggs, 2009; Stroud et al., 2009) and is highly correlated with age, and because age was a significant covariate in the above analyses, we examined whether age might interact with the Group × Symptom Level effects on the diurnal decline in cortisol reported above. To examine this question, we used a regression analysis with diurnal decrease as the dependent factor. EPA/SA versus others, age group, and symptom level were entered as dummy variables, followed two-way interaction terms, and finally the three-way interaction of age, symptom level, and group. Importantly, the results did not yield a significant three-way interaction, $\beta = .01$, $p = .73$, indicating that age did not moderate the overall findings observed involving attenuated diurnal decrease in children with early abuse and high symptoms. Similarly, we considered whether gender would moderate the effects of early abuse and symptom level. An analogous regression analysis, as was conducted for age, also was carried out with gender; however, the three-way interaction of early abuse, symptom level, and gender also was not significant, $\beta = -.01$, $p = .82$, indicating that the effects were not operating differently among boys and girls.

EPA/SA Versus Early Neglect/Emotional Maltreatment

To examine whether other forms of early maltreatment exerted an impact on the diurnal decrease in cortisol, we examined only the children whose maltreatment onset was prior to age 5. There were 151 children who experienced neglect or emotional maltreatment but not physical or sexual abuse, and these children were contrasted with the EPA/SA group. The severity of emotional maltreatment and of neglect did not differ between these two groups. In an ANCOVA using the decrease in cortisol as the dependent measure, the early maltreatment subtype designation and high versus low symptom status were used as grouping factors, and morning level cortisol, age, and gender as covariates. A significant main effect was found for symptom status, $F(1, 204) = 13.13$, $p < .001$; however, this effect was clarified by a significant interaction effect of symptom status and maltreatment type, $F(1, 204) = 7.29$, $p = .007$. To probe this interaction effect, the four groups in the interaction were contrasted with Bonferroni post hoc tests. The interaction effect is shown in Figure 2a. The EPA/SA group with high symptoms ($M = 0.13$, $SD = 0.23$) showed a smaller diurnal decrease than any of the other groups. The difference was highly significant for each of the low depressive symptom groups, early neglect-emotional maltreatment ($M = 0.24$, $SD = 0.17$, $p = .004$) and EPA/SA ($M = 0.27$, $SD = 0.17$, $p = .001$), and was marginally significant for the early neglect, high depressive symptom group ($M = 0.22$, $SD = 0.17$, $p = .10$). No other contrast was significant.

The Effect of Early Versus Late Onset of Physical/Sexual Abuse

We also sought to determine whether EPA/SA was responsible for the observed effects, or whether physical or sexual abuse with later onset also would demonstrate the attenuated diurnal decrease in cortisol. Accordingly, children who experienced the onset of physical or sexual abuse beyond the preschool period were identified ($n = 41$), and these children were contrasted with the EPA/SA group. The severity of physical abuse and of sexual abuse did not differ between these abuse onset groups. In an ANCOVA using the decrease in cortisol as the dependent measure, the abuse onset group and high versus low symptom status were used as grouping factors, and morning level cortisol, age, and gender as covariates. As shown in Figure 2b, a significant interaction between timing of abuse onset (< 60 months, ≥ 60 months) and the presence of high depressive or internalizing symptoms was found, $F(1, 94) = 11.87$, $p = .001$. The interaction was probed through Bonferroni-corrected post hoc comparisons. The EPA/SA group with high symptoms ($M = 0.12$, $SD = 0.24$) had a significantly lower decrease in cortisol than the later abuse/low level symptom group ($M = 0.29$, $SD = 0.20$, $p = .05$) and the EPA/SA group with low level symptoms ($M = 0.27$, $SD = 0.17$, $p = .001$); however, a significant contrast was not found with the later abuse and low level symptom group ($M = 0.21$, $SD = 0.20$, $p = .25$). Other contrasts were not significant. These results again highlight the EPA/SA—high symptom group as uniquely demonstrating a pattern of attenuated diurnal decrease in cortisol.

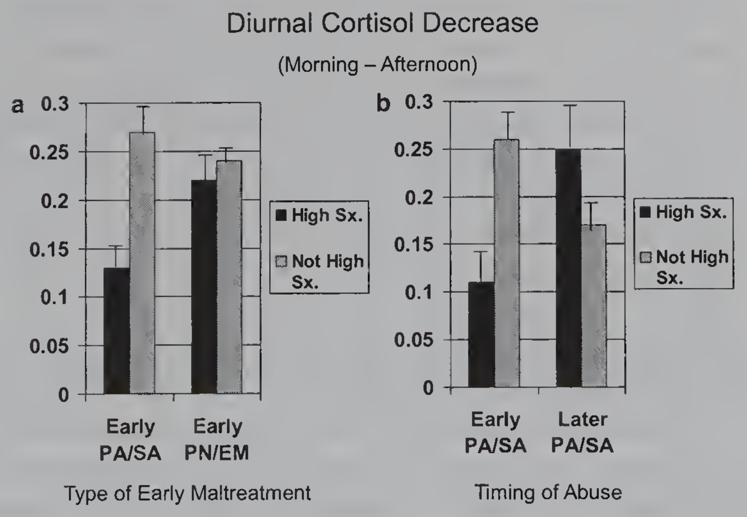

Figure 2. Specificity of diurnal cortisol attenuation for early physical or sexual abuse and high symptoms: Comparisons with early neglect or emotional maltreatment and with later physical or sexual abuse.

Note. Diurnal cortisol decrease values are adjusted for covariates. PA = physical abuse; SA = sexual abuse; PN = physical neglect; EM = emotional maltreatment; Sx. = internalizing and depression symptoms.

Features of Maltreatment Timing, Diversity, and Perpetrator

Finally, we considered whether the onset period of maltreatment, recency of maltreatment, chronicity of maltreatment (number of developmental periods of maltreatment), diversity of maltreatment experiences (number of subtypes of maltreatment), and mother, father, and others as perpetrators of maltreatment provided more discriminating perspectives on the atypical pattern of cortisol change across the day observed in early physically or sexually abused/high symptom children. For each of these seven maltreatment features, analogous repeated measures ANCOVAs were conducted, as had been done with the early abuse group classification. High versus low depressive and internalizing symptom status was included as a second main effect, with age and gender as covariates. We determined if any significant interaction effects for time of day, symptom status, and the respective maltreatment feature were significant in relation to cortisol regulation across the day. None of the maltreatment parameters we considered resulted in a significant interaction effect (*ps* = .26, .46, .32, .19, .48, .16, and .99, for onset, chronicity, recency, diversity, mother as perpetrator, father as perpetrator, and other as perpetrator of maltreatment, respectively).

Discussion

In this investigation we sought to examine whether children experiencing physical or sexual abuse in the early years of life and exhibiting high internalizing symptomatology displayed a unique signature of cortisol levels across the day suggestive of neuroendocrine dysregulation. The results supported our predictions. First, we found that children experiencing abuse in the first 5 years of life exhibited more internalizing symptoms than maltreated children without early abuse and nonmaltreated children of the same socioeconomic level. Second, children experiencing early abuse who had high internalizing symptoms exhibited an atypical flattening of cortisol production over the daytime hours. Further analyses indicated that even among children high on internalizing symptoms, other parameters of maltreatment, including developmental period of onset, recency, chronicity, diversity, and type of perpetrator, did not provide a better explanation of the phenomena than did the experience of EPA/SA.

The pattern of cortisol production noted for the early abused/high internalizing children provided consistent evidence of HPA axis dysregulation as noted in adults and children under chronic stress (Gunnar & Vazquez, 2001; Heim et al., 2008; Miller et al., 2007). That is, we obtained evidence of a less marked decline in cortisol over the daytime due to a slight lowering of AM and slight increase in PM levels. Given the times we were able to sample saliva, it is somewhat remarkable that we were able to detect this pattern of dysregulation. Cortisol is at its daily peak approximately 30 min after morning awakening, drops steeply for the next 30 min to 1 hr, and then declines gradually over the day, until it reaches almost a zero nadir soon after the onset of nighttime sleep (cf. Susman et al., 2007). Most studies that have identified this stress-related pattern of daytime cortisol dysregulation have sampled at morning wake-up and at bedtime. In the present study, in contrast, while we sampled the children at 9 a.m. it is very likely that the children had been awake long enough so that we missed the early morning peak. Although 4 p.m. is late in the afternoon, levels at this time are not as low as the nadir that they will reach later in the evening. Thus, it is possible that the pattern we noted would have been even more marked had we been able to sample earlier and later in the day.

Whereas the pattern we noted is not the same as that seen among adults with clinical depression, the findings are consistent with those described in two other reports on depressed, maltreated children studied in a day camp setting (Hart et al., 1996; Kaufman, 1991). Hart et al., (1996) found that maltreated children who were also depressed showed a less marked diurnal decrease in cortisol from 9 a.m. to 4 p.m., although no attempt was made in that study to differentiate patterns based on subtype of maltreatment. Kaufman (1991) noted that maltreated and depressed children in her sample were less likely than nondepressed maltreated children to show a decrease in cortisol from 9 a.m. to 4 p.m. Notably similar to the present study, she also observed that the depressed maltreated children were more likely to have suffered abuse in addition to neglect, rather than solely neglect. Neither the Hart et al. study nor the Kaufman study examined the influence of the developmental timing of maltreatment subtypes.

We also found that both gender and age were associated with morning to afternoon change in cortisol level. Whereas girls had significantly lower afternoon cortisol and greater diurnal decrease than boys, gender did not moderate the effects of EPA/SA and high symptoms. In terms of age, consistent with the literature, older children were found to have significantly higher morning cortisol levels and a greater morning to afternoon cortisol decrease than younger children. However, age did not moderate the overall effects of EPA/SA and high symptoms. Thus, the findings are generally applicable for boys and girls, as well as for children across the age range studied.

The results of this investigation also contribute to our knowledge of pathways to depressive and internalizing symptomatology. For example, Kaplow and Widom (2007) reported that an earlier occurrence of maltreatment, defined as onset of maltreatment in the first 5 years of life, predicted more symptoms of anxiety and depression in adulthood. Our findings suggest that the results of Kaplow and Widom may have been even more compelling if they had been able to examine physical abuse, sexual abuse, and neglect separately. However, both the Kaplow and Widom and the current investigation raise the question as to why an early onset of maltreatment, and in our case abuse, is more predictive than a later onset in increasing risk for internalizing and depressive symptomatology and, in the context of these symptoms, dysregulated patterns of diurnal cortisol production. Early abuse may be more damaging to developing emotion and stress systems because it occurs during periods of rapid neurodevelopment (Cicchetti & Walker, 2001; Gunnar & Vazquez, 2006). Very young children also may be less able than older children to discern the cues predictive of an abusive attack, and this lack of predictability may engender chronic stress and hypervigilance to aggression in these youngsters, even when abusive events are not occurring (Rieder & Cicchetti, 1989; Teisl & Cicchetti, 2008). School-aged physically abused children, on the other hand, have been shown to be highly sensitive to even very degraded signals of threat, which although potentially maladaptive in some contexts, may provide some relief from constant vigilance in the abusive home (Pollak, Cicchetti, & Klorman, 1998; Pollak & Sinha, 2002; Shackman, Shackman, & Pollak, 2007). In addition, the impact of EPA/SA on developing brain systems may be especially pernicious because it occurs during a period when the child is nearly wholly dependent on parents for survival. For the abused infant, toddler, or preschooler, a hypervigilant state of mind and chronic stress with respect to unpredictable parental attacks may shift neurobiological development onto pathways leading to depression and neuroendocrine dysregulation (Cicchetti & Rogosch, 2001; Tarullo & Gunnar, 2006).

Another question pertains to why early neglect in the absence of physical or sexual abuse did not have a significant impact on either internalizing and depressive symptoms or HPA axis activity. While early neglect has been shown to have marked impacts on young children's social and cognitive competence (Pears & Fisher, 2005), neglect experiences may not be as fear and threat arousing as are the experiences of being physically attacked and hurt. Although it is not uncommon to find early neglect in the absence of abuse, it is rare to find early abuse in the absence of neglect, especially in low-income samples such as the one we studied. Nearly three fourths of our EPA/SA sample also was neglected and emotionally maltreated. We do not know whether their neglect and emotional maltreatment contributed to their increased internalizing symptomatology and HPA dysregulation; however, it is possible that neglect made these children even more vulnerable to the fear and stress engendered by early abuse.

It is also conceivable that our findings may have been even more striking if we had included maltreated children who were residing in foster care. Generally children who experience early and extreme maltreatment are removed from their homes and placed in foster care. Because we excluded children with out-of-home placements, it is likely that we did not include the most extreme cases. This is not to say that the maltreated children in our sample experienced only mild abuse. Indeed, the median physical or sexual abuse severity score as coded using the MCS for the early abused children was 3 on the scale of 5 points, corresponding to incidents involving the infliction of marks on a child's face, serious bruises, or fondling a child for sexual gratification. Rather, by excluding children with out-of-home placements, we avoided confounding the impact of maltreatment with the stress of transitions in and out of foster care homes. These changes may be important in the sequelae of emotion and neuroendocrine dysregulation for many maltreated children (Gunnar & Fisher, 2006; Kaufman, 1991). Studying preschool children who had primarily experienced neglect, Bruce, Fisher, Pears, and Levine (in press) found reduced morning cortisol in the first months following a new foster placement. A year or more later, however, whether or not the morning cortisol recovered, continued to be dysregulated, or became more dysregulated depended on whether the children were randomly assigned to regular foster care or to a foster care intervention condition that stabilized their early care (Fisher, Stoolmiller, & Gunnar, 2007). Thus, the Bruce et al. study revealed the sensitivity of cortisol regulation to transient impacts of neglect and relationship disruption, while the present study indicated the long-term impacts of EPA/SA in the absence of the child being removed from the home.

Consistent with the results of Heim et al. (2008), the combination of high depressive symptoms and EPA/SA appeared to be critical to dysregulation of the HPA axis. Early physically and sexually abused children who were low on depressive and internalizing symptoms had cortisol patterns that were comparable to other maltreated and nonmaltreated children. However, whereas Heim et al. examined reactions of the HPA axis to psychosocial stressors and pharmacological challenges, we addressed only the children's typical daytime pattern of cortisol production. We do not know whether the high internalizing, early abused children also would show larger or more prolonged cortisol responses to a stressor task similar to the adult women in the Heim et al. study. This awaits further research. It also will be important to conduct longitudinal studies in order to ascertain whether the dysregulated pattern of cortisol production noted among these high internalizing/early abused children presages ongoing patterns of neurobiological and neuroendocrine dysregulation as the children develop.

There are many parallels between the neurobiological effects of early abuse and those of MDD (Heim et al., 2004; Heim et al., 2008). It is likely that prior investigations of individuals with MDD have included persons who had experienced early abuse (Bemporad & Romano, 1992; Heim et al., 2008). As such, many of the established neurobiological findings in depression may be due to the undetected presence of EPA/SA (Heim et al., 2004). In the absence of early abuse, depression may not be related to changes in the HPA system. Thus, there may be different neurobiological subtypes of depression. Accordingly, a history of early abuse, as well as the clinical presentation, onset, and course of depression should be incorporated into the formulation of potential etiological models of mood disorder (Heim et al., 2004; Heim et al., 2008). For example, because cortisol dysregulation rarely occurs in depressed children who did not experience abuse early in life (Feder et al., 2004), childhood depression without EPA/SA may be caused by different processes and have different neurobiological features than childhood depression with early abuse. Our findings that nonmaltreated children with high levels of depressive or internalizing symptomatology did not exhibit atypical cortisol regulation attest to this divergence. There may be biologically distinct subtypes of depression as a function of the presence or absence of abuse early in life (cf. Heim et al., 2004; Heim et al., 2008). Thus, not all individuals with depression exhibited cortisol dysregulation; we found it only for the early physically or sexually abused children with high internalizing and depressive symptomatology—a group that is more likely to have dysfunctions in early neurobiological development through the high allostatic load caused by abuse.

It is also important to note that not all of the children who experienced early abuse had high depressive or internalizing symptoms. Why is the HPA axis functioning of this group of early abused children better regulated than that of early abused and depressed children with the attenuated diurnal decrease in cortisol? It is likely that there are genes that increase the probability of depression and internalizing problems under conditions of high stress such as EPA/SA. For example, a number of investigations have demonstrated that the s/s and s/l genotypes of the serotonin transporter gene linked promoter region (5-HTTLPR), in interaction with severe child maltreatment, are associated with increased risk for depression in children, adolescents, and adults (see, e.g., Caspi et al., 2003; Cicchetti, Rogosch, & Sturge-Apple, 2007; Kaufman, Cook, Amy, Jones, & Pittinsky, 2004). Conversely, the l/l genotype of the 5-HTTLPR may confer a protective function by decreasing the probability that individuals experiencing severe maltreatment will develop depression (Cicchetti et al., 2007; Kaufman et al., 2004). Consistent with calls for a multiple levels of analysis approach to investigating the determinants of resilience (Charney, 2004; Cicchetti & Curtis, 2007; Curtis & Cicchetti, 2003), future research will need to include assessments of potential genetic dispositions to depression to discover whether individuals experiencing EPA/SA may have the genes that confer vulnerability or protection against depression (see also Bradley et al., 2008). Similarly, it will be important in subsequent investigations to examine the contribution that the CRH genes and the glucocorticoid receptor genes play in individual differences in HPA axis activity, regulation, and reactivity.

There are several limitations in the design that deserve discussion. First, it is impossible to isolate completely the effects of physical and sexual abuse from those of neglect. The clinical reality is that there is an extremely high overlap and that neglect is almost a consistent experience for these children, particularly in low-income samples. Thus, some caution is warranted in interpreting the meaning of our subtype findings. It may be, as we argued above, that abuse (physical or sexual) has features (e.g., provoke feelings of fear) that are particularly potent in activating stress and emotion pathways and thus in dysregulating rapidly developing stress and emotion neurobiological systems. However, it could also be that abuse in the context of neglect is a more severe form of maltreatment and thus that "severity" rather than particular features (e.g., fear provoking) produced the effects we observe. As abuse and neglect are nearly impossible to disentangle in human populations, it may prove useful to translate the findings from the current study back into animal models that compare early abuse, early abuse and early neglect, early neglect only, and later abuse and neglect.

Another limitation in the study was our lack of information about the time when the children awoke. Cortisol levels change markedly in the 1st hour after morning awakening and then gradually decrease over the remainder of the day. Levels are more closely related to the individual's wake-up time than to clock time. We chose not to measure wake-up time because we anticipated errors in child reporting of this measure, given the high level of disorganization in many of the families' homes. However, in future studies determining a valid method of obtaining individual wake-up times would be helpful. Note, however, that in order for differences in wake-up time to have explained our results, high symptom children with physical or sexual abuse prior to age 5 would have to have woken up earlier than all the other children. Although it is possible, it seems unlikely that this was the case.

A third limitation was that we did not obtain puberty-stage data on these children. Puberty is associated with increases in cortisol levels and reactivity to stressors (Gunnar et al., 2009; Stroud et al., 2009). Undoubtedly some of the older children in our study were entering puberty and this may have influenced their cortisol levels. In the absence of pubertal measures, we used age group (under age 10, age 10, and older) as a proxy measure, and as reported earlier, we did not find that age level moderated the effects of early abuse and high symptoms. Thus, we do not have evidence that pubertal development in the current sample had a major impact on the findings.

Finally, we cannot ascertain whether differences in the diurnal decrease in cortisol of the magnitude we observed will be predictive of future physical or mental health risks in children. There is increasing interest in the impact of chronic stress on patterns of diurnal HPA axis activity. Several studies of adult cohorts now show that "flattening" of the diurnal decrease in the same range as we observed predicts heightened risk of impairment in cardiovascular and immune system functioning (Heim et al., 2008; Raison & Miller, 2003). Thus it is conceivable that variations in the diurnal decrease in the range we report reflect mechanisms that have health consequences. Nonetheless, we cannot conclude that this is the case without longitudinal studies.

Our findings possess significant implications for children within the child welfare population, particularly with respect to the importance of early preventive interventions for children who have been abused or neglected even in the absence of clinical levels of depressive or internalizing symptomatology. In addition, intervention, timed as closely as possible to the early abusive experience, could be implemented to prevent the recidivism of maltreatment, to redirect the abused children onto a positive developmental trajectory, and to prevent the emergence of depression (Cicchetti, Rogosch, & Toth, 2006; Toth & Cicchetti, 1993). Because HPA axis dysregulation in early abused children with depression may reflect a unique subtype of depression, differential responses to treatment modalities may emerge, and this is an area requiring further investigation. Given what we know about the effects of cortisol dysregulation on a wide array of neurobiological systems, as well as on physical health and cognitive processes, the results of this investigation also have significant public health implications.

This study examined the direct and interactive effects of stress reactivity and family adversity on socioemotional and cognitive development in three hundred and thirty-eight 5- to 6-year-old children. Neurobiological stress reactivity was measured as respiratory sinus arrhythmia and salivary cortisol responses to social, cognitive, sensory, and emotional challenges. Adaptation was assessed using child, parent, and teacher reports of externalizing symptoms, prosocial behaviors, school engagement, and academic competence. Results revealed significant interactions between reactivity and adversity. High stress reactivity was associated with more maladaptive outcomes in the context of high adversity but with better adaption in the context of low adversity. The findings corroborate a reconceptualization of stress reactivity as *biological sensitivity to context* by showing that high reactivity can both hinder and promote adaptive functioning.

A substantive body of work has established that environmental adversity can have a deleterious effect on children's functioning (Luthar, 2006; Obradović, Shaffer, & Masten, in press; Rutter, 1983; Sameroff, 2006). Exposure to adverse, stressful events, such as marital conflict, maternal depression, and financial stress, has been linked to socioemotional behavior problems and cognitive deficits (Boyce, 2007; Boyce et al., 2001; Burchinal, Roberts, Hooper, & Zeisel, 2000; Cummings & Davies, 2002; Essex, Klein, Cho, & Kalin, 2002; Masten & Shaffer, 2006). Nevertheless, not all children are equally susceptible to adverse environmental influences. In accordance with the "stress diathesis" hypothesis, behaviorally or biologically reactive children have been traditionally identified as particularly vulnerable to stressful experiences, showing higher levels of behavioral and health problems than their low-reactive peers in the context of environmental risk and adversity (Belsky, Hsieh, & Crnic, 1998; Cummings, El-Sheikh, Kouros, & Keller, 2007; Deater-Deckard & Dodge, 1997; El-Sheikh, 2005; Ramos, Guerin, Gottfried, Bathurst, & Oliver, 2005). In recent years, however, a few researchers have challenged this traditional view, arguing that high reactivity, whether measured at the emotional, behavioral, or biological level, is not a unitary, pathogenic response to adversity that invariably leads to maladaptation. Belsky and colleagues (Belsky, Bakermans-Kranenburg, & van IJzendoorn, 2007), for example, have posited that temperamentally

reactive children may show higher susceptibility to environmental influences "for better and for worse." That is, reactive children may be more vulnerable to contextual risk, but they may also show more adaptive responses to interventions (Blair, 2002; Klein Velderman, Bakermans-Kranenburg, Juffer, & van IJzendoorn, 2006). Similarly, Boyce and colleagues have proposed a new theory suggesting that stress reactivity is better conceptualized as a high biological sensitivity to context (Boyce, 2007; Boyce & Ellis, 2005). From this theoretical perspective, children with heightened biological sensitivity to context are predicted to be more vulnerable to negative and stressful contextual factors, but also to have greater capacity to benefit from positive environmental influences. Thus, high biological sensitivity may be maladaptive in the context of adversity but adaptive in the context of a nurturing and supportive environment (Boyce, 1996; Boyce et al., 1995; Boyce et al., 2006; Ellis, Essex, & Boyce, 2005). This work underlines the importance of understanding more fully the biological processes that interact with environmental influences to shape children's adaptation, as indexed by competence and psychopathology (Curtis & Cicchetti, 2003; Masten & Obradović, 2006). The current study was designed to examine how early exposure to family adversity interacts with children's stress reactivity to predict indices of socioemotional behavior, school engagement, and academic competence.

Human Stress Response

Every day, in all human societies, children are exposed to challenging or stressful events from multiple sources. These events range from normative, potentially positive events, such as forming a new peer group; to adverse events, such as witnessing marital conflict; and truly traumatic events that directly threaten children's well-being, such as abuse and neglect. Children respond to these stressors with a set of highly integrated, neurobiological stress responses. A "fight-or-flight" response activates the autonomic nervous system (ANS), which initiates, within seconds, an integrated, short-onset repertoire of biobehavioral changes associated with accelerations of heart and respiratory rates, sweat production, and other physiological changes. The ANS comprises both a sympathetic (SNS) branch, which initiates physiological arousal, and a parasympathetic (PNS) branch, which modulates SNS input to the heart and other target organs, regulating recovery and restoring autonomic homeostasis (Berntson, Cacioppo, & Quigley, 1993). In a lagged response occurring within minutes, activation of the hypothalamic–pituitary–adrenocortical (HPA) axis via glucocorticoid secretion regulates glucose metabolism, blood pressure, and immunity and counterbalances the effects of the integrated ANS stress response (Sapolsky, Romero, & Munck, 2000). There are numerous ways of assessing children's stress reactivity. Because of our interest in whether stress reactivity moderates the effects of adversity on indices of psychopathology and competence, we examined two indicators of stress reactivity that are known to play a role in regulating stress-induced arousal and maintaining homeostasis: (a) respiratory sinus arrhythmia (RSA) and (b) salivary cortisol.

Respiratory Sinus Arrhythmia

RSA is a measure of parasympathetic stress response and refers to high-frequency heart rate variation controlled by efferent fibers of the vagus nerve during the respiratory cycle. Vagal regulation, in the form of increases and decreases in RSA, has been regarded as an index of children's capacity to regulate responses to positive and negative environmental demands (Beauchaine, 2001; Beauchaine, Gatzke-Kopp, & Mead, 2007; Porges, 2001, 2003, 2007). High levels of basal RSA have been associated with social competence, empathy, and emotion regulation (Beauchaine, 2001; Eisenberg et al., 1995; Fabes, Eisenberg, & Eisenbud, 1993; Fox & Field, 1989). Low basal RSA, on the other hand, may indicate emotional lability and dysregulation and has been linked to behavior problems in at-risk or clinical samples (Beauchaine, 2001; Beauchaine et al., 2007; Field et al., 1996; Mezzacappa et al., 1997; Pine et al., 1996; Pine et al., 1998). However, it is important to note that recent studies of community, nonclinical samples have found a positive relation, or no significant relation, between resting RSA and externalizing symptoms (Calkins, Graziano, & Keane, 2007; Dietrich et al., 2007).

Further, researchers have examined changes in RSA in response to stressful laboratory challenges. High reactivity, as indexed by decreases in RSA from basal levels (i.e., greater vagal withdrawal), has been associated with more sustained attention, better emotion regulation, and increased engagement during challenging tasks (Calkins, 1997; Suess, Porges, & Plude, 1994). However, in community samples of kindergarten children, higher RSA reactivity to various challenge tasks has been linked to seemingly contradictory indices of adaptation, such as high levels of sociability (Doussard-Roosevelt, Montogomery, & Porges, 2003) and internalizing symptoms (Boyce et al., 2001). Some of the inconsistencies across studies might be explained by the nature of the sample. For example, low RSA reactivity has been associated with externalizing symptoms in normative samples of young children (Boyce et al., 2001; Calkins et al., 2007), whereas high RSA reactivity in response to emotional stimuli has been observed in children with clinical levels of behavior problems (Crowell et al., 2005).

Only a few studies have examined the effect of RSA in the context of both high and low adversity. Several studies of community samples indicate that high basal RSA levels and high RSA reactivity in response to emotion-evoking stimuli (e.g., an adult argument) buffered children from the effects of marital conflict on behavior problems, academic achievement, and health (El-Sheikh, Harger, & Whitson, 2001; El-Sheikh & Whitson, 2006; Katz & Gottman, 1995, 1997). Only children with low baseline RSA and RSA reactivity were at risk for maladaptation in the context of high marital conflict. However, these findings varied across gender, type of marital conflict (e.g., verbal, physical), and children's outcomes. Similarly, high RSA reactivity to interpersonal stress emerged as a protective factor against the effects of hostile-withdrawn parenting on peer conflict but not on positive indices of peer interactions (Leary & Katz, 2004). In contrast, in a clinical sample, parental psychopathology had a negative effect on children's emotional and behavioral problems only in children with high baseline RSA (Shannon, Beauchaine, Brenner, Neuhaus, & Gatzke-Kopp, 2007). Studies examining other indices of ANS stress reactivity (i.e., heart rate, blood pressure, skin conductance) in community samples also indicate that children with high stress reactivity may be at risk for social, cognitive, behavioral, and health problems in the context of high adversity but may show better developmental outcomes in the context of low adversity (Boyce, 1996; Boyce et al., 1995; Boyce et al., 2006; Cummings et al., 2007; El-Sheikh, 2005).

In sum, the effect of stress reactivity on adaptation seems to be context dependent, but the directions of reactivity effects across different contexts remain unclear. Further studies are needed to elucidate the role of RSA reactivity in the development of competence and psychopathology, bearing in mind the limitations of previous research. First, many existing studies of RSA reactivity have important methodological flaws, such as a lack of appropriate controls for respiratory rate, attention, and motor activity (Beauchaine, 2001). Second, RSA reactivity has been examined mostly in relation to a single challenge, potentially misrepresenting the comprehensive reactivity to various types of challenges that children may encounter in their daily lives. Third, studies have often focused on a single source of adversity, such as marital conflict, yet children face various kinds of adversities in family environments. Fourth, studies of stress reactivity in general have been largely focused on measures of behavioral and health problems to the exclusion of more positive and prosocial indicators of adaptation.

Cortisol and Adaptive Functioning

Cortisol is the human glucocorticoid hormone secreted by the adrenal glands and passively diffuses into saliva. Salivary cortisol reflects the levels of unbound and biologically active cortisol circulating in the blood. As with RSA, researchers have linked individual differences in both basal and reactive cortisol expression primarily to indices of behavior problems (Gunnar & Vazquez, 2006). In general, in both clinical and community samples, elevated daily cortisol levels have been associated with internalizing symptoms (Goodyer, Herbert, & Althan, 1998; Klimes-Dougan, Hastings, Granger, Usher, & Zahn-Waxler, 2001), whereas lower levels of daily cortisol have been associated with externalizing symptoms (Hardie, Moss, Vanyukov, Yao, & Kirillovac, 2002; King, Barkley, & Barrett, 1998; McBurnett, Lahey, Rathouz, & Loeber, 2000; McBurnett et al., 1991; Moss, Vanyukov, & Martin, 1995; Shirtcliff, Granger, Booth, & Johnson, 2005). However, in community samples of kindergarten children, basal cortisol secretion was positively related to internalizing symptoms, social wariness, and symptom severity (Essex et al., 2002; Smider et al., 2002).

A few studies have examined cortisol reactivity to specific laboratory challenges. Moderate elevation of cortisol in response to cognitive tasks has been associated with better executive functioning and self-regulation skills in both middle- and low-income samples (Blair, Granger, & Razza, 2005; Davis, Bruce, & Gunnar, 2002). In addition, high cortisol reactivity in response to parent–child conflict tasks has been associated with social problems and internalizing symptoms in clinical samples (Granger, Weisz, & Kauneckis, 1994; Granger, Weisz, McCracken, Ikeda, & Douglas, 1996). However, differences in sample characteristics and stimuli across these studies preclude any conclusions regarding the relation between cortisol reactivity to different challenges and adaptive functioning.

Studies examining cortisol changes over a day in child care or preschool in community samples have linked elevated cortisol to impulsivity, poor effortful control, peer rejection, and aggression (Dettling, Gunnar, & Donzella, 1999; Dettling, Parker, Lane, Sebanc, & Gunnar, 2000; Gunnar, Sebanc, Tout, Donzella, & van Dulmen, 2003). Similarly, elevated cortisol in response to starting a new school year has been associated with negative affectivity, and surgency and extraversion (Davis, Donzella, Krueger, & Gunnar, 1999). However, a more complex picture emerged from a study that measured children's cortisol response during the first weeks of school, when children forge new peer groups and connections, and again later in the school year, when peer groups have been fully formed (Gunnar, Tout, de Haan, Pierce, & Stansbury, 1997). Children showing elevated cortisol expression during the first weeks of school and normal levels later in the year were rated as extraverted, socially competent, and outgoing, whereas children who showed high levels of cortisol later in the school year showed more solitary and negative behaviors and were seen as less competent and less outgoing.

Although these studies indicate that the relation between cortisol reactivity and adaptation may be context dependent and may vary with levels of contextual stress, there is a paucity of studies examining the interactive effects of cortisol and adversity on adaptation. We are aware of only one such study, which shows that cortisol reactivity is related to symptom severity only for children with low father involvement in infancy (Boyce et al., 2006). Moreover, studies examining cortisol response to various age-appropriate stressors and in the context of overall family adversity are rare. Thus, it is unknown whether cortisol reactivity may diminish or amplify the effects of adversity on children's adaptation. In order to better understand the regulatory function of cortisol, researchers need to examine whether cortisol reactivity interacts with contextual factors in predicting both positive and negative developmental outcomes.

Current Study

The main goal of this study was to investigate how the interplay between children's stress reactivity and overall family adversity influences adaptation. We focused our study on kindergarten children because understanding processes that subserve adaptation during the salient developmental transition to a school setting is very important, given the reverberatory effects that early behavior problems or academic failure can have on later developmental trajectories. Consequently, we examined adaptation across four domains of functioning known to contribute to early school success and later adjustment: (a) externalizing symptoms, (b) prosocial behaviors toward peers, (c) school engagement, and (d) academic competence.

Based on the broad literature on risk and adversity, we hypothesized a robust negative main effect of family adversity across all indices of adaptation. We also expected to find main effects of stress reactivity on adaptation, but given the simultaneous test of interactive effects, as well as the paucity of studies examining the effects of RSA and cortisol reactivity, especially for positive developmental outcomes, and some inconsistencies within such studies, we did not hypothesize the directions of these main effects. More importantly, in accordance with the theory of biological sensitivity to context (Boyce & Ellis, 2005; Ellis et al., 2005), we expected to find evidence that ANS and HPA reactivity moderate the effects of early family adversity on various domains of functioning. We hypothesized that in high-adversity family environments, elevated levels of stress reactivity would be associated with maladaptive outcomes, whereas low stress reactivity would act as a protective factor. In the context of low family adversity, on the other hand, we expected high levels of reactivity to be associated with better adaptation. It is important to note that although biological sensitivity to context should be examined in both positive and negative settings, our assessment focuses on six types of family adversities, and a lack of overall family adversity does not necessarily imply a supportive and nurturing environment. In addition to the hypothesized Adversity × Stress Reactivity interactions, we controlled for children's sex and tested whether main and interactive effects of adversity and reactivity vary across sex.

Method

Participants

The sample included 338 children (163 females, 175 males) who participated in a longitudinal study of social status, biological responses to adversity, and child mental and physical health. Participants were recruited in three waves from 29 kindergarten classrooms within six public schools in the San Francisco Bay Area (Oakland, Albany, and

Piedmont Unified school districts) during the falls of 2003, 2004, and 2005. Schools were selected to represent a variety of sociodemographic and ethnic characteristics of the metropolitan area. Families were recruited through a series of efforts that included home mailings, presentations at kindergarten parent welcome nights, and in-person recruitment during drop-off and pick-up. Every family with a child in the target classrooms was invited to participate. However, families who were not fluent in either English or Spanish were excluded to ensure adequate comprehension of study questionnaires. Schools were provided with $20 per child enrolled in the study.

The mean age of the children at the kindergarten entry was 5.32 years (*SD* = 0.32, range = 4.75–6.28). The sample was ethnically diverse, and children were identified as 19% African American, 11% Asian, 43% European or White, 4% Latino, 22% multiethnic, and 2% as "other" ethnicity. Family demographic information was not provided by 16 families. Primary caregivers were 87% biological mothers, 9% biological fathers, 2.5% adoptive mothers, 0.6% biological grandmothers, and 0.9% "other" relations. As the vast majority of primary caregivers were parents, these terms are used interchangeably here. Average annual household income ranged from < $10,000 to > $400,000 (*M* = $60,000–79,999; *Mdn* = $80,000–99,999). Highest level of educational attainment in the household ranged from less than a high school diploma to advanced degrees, with 75% of caregivers having at least a college degree.

Procedures

Data for this study were collected in the fall (Time 1) and spring (Time 2) during the kindergarten year. Parents' informed consent and children's assent were obtained prior to the start of data collection. Parent report of family adversity and children's functioning was collected through a series of home mailings, and families were compensated with $50 for each completed time point. Teacher report of children's functioning was collected through questionnaires dropped off and picked up at the child's school, and teachers were compensated $15 per child for each report returned. Self-report of children's functioning was collected through a series of structured, scripted interviews conducted in a separate, quiet room at elementary schools.

In addition, children participated in the 20-min reactivity protocol, which included four age-appropriate tasks designed to elicit stress responses to social, cognitive, sensory, and emotional challenges (Alkon et al., 2003; Boyce et al., 1995). Since PNS can be activated by psychomotor activity, such as gesturing, speaking, focused attending, and nonchallenging social engagement (Bazhenova & Porges, 1997; Bernardi et al., 2000; Berntson, Cacioppo, & Fieldstone, 1996; Porges, 2001; Porges et al., 2007), RSA assessed during a challenge task reflects both stress reactivity in response to the challenge and reactivity in response to the psychomotor or engagement demands of the challenge task. The recent literature has emphasized the importance of maximizing the mobilization of the psychological response to the particular challenge and minimizing the peripheral triggers of cardiovascular activation (Bush, Alkon, Obradović, Stamperdahl, & Boyce, 2009; Kamarck & Lovallo, 2003). Thus, in order to best measure the psychophysiological response to the four challenges, each challenge, task in the reactivity protocol was preceded by a nonchallenging "control task" that paralleled the motor and engagement demands of that challenge, and levels of autonomic arousal during the control tasks were used as baseline values.

The autonomic reactivity protocol started with an experimenter reading a calming short story (2 min). Next, the child completed four sets of paired tasks, each consisting of a control condition and challenge condition. The *social challenge task* (2 min) was a structured interview about the child's family, friends, and likes/dislikes adapted from the Gesell School Readiness Screening Test (Carlson, 1985). This was preceded by the *social control task* in which children were asked to name common animals and colors from a picture book to capture arousal associated with speaking, gestures during social speech, and attention involved in social engagement (2 min). The *cognitive challenge task* (2 min) was a digit span recitation task derived from the Kaufman Assessment Battery for Children (Kaufman & Kaufman, 1983) in which children were asked to recall sequences of numbers up to six digits in length and received negative verbal feedback after making a mistake. This was preceded by the *cognitive control task* in which children were asked to repeat simple, one- or two-digit number sequences to capture arousal associated with listening, speaking numbers, and social engagement (1 min). The *sensory challenge task* (1 min) was a taste-identification task (Kagan & Snidman, 1991) during which children were asked to identify two drops of concentrated lemon juice placed on their tongues. This was preceded by the *sensory control task* in which children were asked to identify two drops of water placed on their tongues to capture arousal associated with mouth opening and swallowing, anticipation, and guessing the content of the liquid (1 min). The *emotional challenge task* (2 min) consisted of watching a short emotion-evoking movie clip chosen to elicit fear (Eisenberg et al., 1988). This was preceded by the *emotion-control task* in which children were asked to watch an emotionally neutral movie clip to capture physiological responding associated with attending to visual stimuli (2 min). The autonomic reactivity protocol concluded with the reading of another calming story (2 min).

Measures

Stress reactivity. Children's stress reactivity was assessed using changes in both RSA and *salivary cortisol* during the stress reactivity protocol. After the child was familiarized with the equipment, four spot electrodes (two current, two impedance) were placed in the standard tetrapolar configuration on the child's neck and chest, and ECG electrodes were placed on the right clavicle and lower left rib. A 4 mA AC current at 100 kHz was passed through the two current electrodes. RSA was monitored continuously during the protocol. Data were acquired using the Biopac MP150 (Biopac Systems, Santa Barbara, CA) interfaced to a PC-based computer. Analog data were continuously monitored on the computer for signal and noise, and digitized data were stored for offline analysis. RSA was derived in accordance with recommendations of the Society for Psychophysiological Research committee on heart rate variability (Berntson et al., 1997). The sampling frequency was 1 kHz. Prior to analyses, each waveform was verified, IBIs were visually checked, and artifacts were identified using Berntson, Quigley, Jang, and Boysen's (1990) algorithm within the MindWare software program (http://www.mindwaretech.com). RSA was estimated as the natural logarithm of the variance of heart period within the high-frequency bandpass associated with respiration at this age (i.e., 0.15–0.80 Hz; Bar-Haim, Marshall, & Fox, 2000; Rudolph, Rudolph, Hostetter, Lister, & Siegel, 2003). Outlier data were checked and verified minute by minute if they were > 3 *SD* from the group mean. Mean RSA magnitude was calculated for each 1-min interval and averaged within each task (Cacioppo, Uchino, & Berntson, 1994).

RSA reactivity responses during each of the control tasks were used as baseline reference values to create four task RSA reactivity scores. To control for the influence of baseline levels of arousal, we created four standardized residual scores as measures of reactivity to social, cognitive, sensory, and emotional challenges by regressing RSA values during the challenge tasks on the respective control task RSA values. Residuals reflect the extent to which an individual's physiologic response deviated from the regression line derived from sample responses (Manuck, Kasprowicz, & Muldoon, 1990). The four standardized residual scores were then averaged to create one index of RSA stress reactivity. Elevated RSA reactivity was represented by negative residual scores, indicating a decrease in RSA and vagal withdrawal in response to a given challenge. Conversely, low reactivity was represented by positive residual scores, indicating an increase in RSA and vagal activation in response to the challenge.

Descriptive statistics for RSA responses to tasks are presented in Table 1. Average RSA differences between challenge and control tasks were −0.25 (*SD* = 0.66) for the social challenge, 0.60 (*SD* = 0.67) for the cognitive challenge, −0.32 (*SD* = 0.84) for the sensory challenge, and 0.10 (*SD* = 0.47) for the emotional challenge task. RSA reactivity levels were significantly different from zero during the social ($t = -6.99$, $p < .001$), cognitive ($t = 16.40$, $p < .001$), sensory ($t = -7.05$, $p < .001$), and

Table 1
Descriptive Statistics for Stress Reactivity and Adversity Variables

Variable	Scale	Min.	Max.	*M*	*SD*
RSA					
Social control		3.29	9.65	6.81	1.12
Social challenge		3.47	10.26	6.56	1.10
Cognitive control		2.62	9.69	6.12	1.20
Cognitive challenge		3.35	9.82	6.72	1.10
Sensory control		2.77	9.91	6.98	1.13

emotional ($t = 4.04$, $p < .001$) tasks. Averaged across the four challenge tasks, 47.1% of the sample showed a decrease in RSA from the levels elicited by the control tasks, suggesting that about half of the sample showed vagal withdrawal in response to challenges. Thus, the reactivity protocol effectively captured variability in child RSA responses to challenges.

At the beginning and end of the reactivity protocol, salivary cortisol was collected by instructing the child to chew on a cotton roll for 20–30 s. Wet cotton rolls were deposited in salivette tubes and stored at −7 °C until assayed. The cortisol samples were assayed using a commercial immunoassay with chemiluminescence detection (Cortisol Luminescence Immunoassay; IBL-Hamburg, Hamburg, Germany). The detection limit of the assay was 0.41 nmol/L. The mean interassay and intra-assay variations were 8.5% and 6.1%, respectively. Cortisol values above 55 nmol/L (< 1% of samples) were considered unreliable data and were discarded. Ten children in this sample were taking medications, such as human growth hormone and exogenous glucocorticoids, known to alter salivary cortisol levels (Masharani et al., 2005). These children were excluded from analyses of cortisol reactivity. Given that cortisol levels in saliva reach their peak approximately 15–20 min following stressor onset, cortisol values collected at the beginning of the session were considered baseline reference values, as they indexed children's cortisol expression in the familiar context of the kindergarten classroom. The average session lasted 27 min (SD = 3 min, range = 19–38 min). Thus, cortisol values collected at the end of the session were considered a measure of reactivity to a novel, mildly stressful context (e.g., strange experimenter, electrodes, challenge tasks), at the midpoint of the reactivity protocol. Descriptive statistics for pre- and postprotocol values are presented in Table 1. We created standardized residual scores by regressing postprotocol cortisol values on preprotocol, baseline values. Because cortisol collection occurred both in the morning and in the afternoon, we examined whether cortisol reactivity varied across the day, due to the known circadian activity of the HPA system. The time of collection was related to absolute preprotocol values ($r = .18$, $p < .01$) but not to postprotocol values and cortisol reactivity as indexed by standardized residual scores, which is consistent with the current literature (Kudielka, Schommer, Hellhammer, & Kirschbaum, 2004). Length of the session also did not significantly relate to cortisol reactivity. Mean cortisol levels pre- and postprotocol were 5.10 nmol/L ($SD = 3.51$) and 4.70 nmol/L ($SD = 3.93$), respectively. Mean difference between pre- and postprotocol values was −0.40 nmol/L ($SD = 3.81$). Positive cortisol reactivity values indicate a stress response, and 37.5% of the sample showed such a response to the challenge protocol. The average difference between pre- and postprotocol values for the responder group was 2.58 nmol/L ($SD = 3.86$).

Adversity. Children's exposure to adversity was assessed by six indices of potential sources of family stress. All measures of adversity were based on parent report, and reliability statistics are reported for the current sample. *Financial Stress* was assessed with four items derived from Essex et al. (2002) that measured parents' thoughts about money problems, difficulty paying bills, and limited opportunities due to lack of finances ($\alpha = .81$) *Parenting Overload* was assessed with five items derived from Essex et al. that measured feelings of being overwhelmed with parenting duties, juggling conflicting obligations, and lacking time to rest or pursue desired activities ($\alpha = .79$). *Marital Conflict* was assessed using the 10-item O'Leary–Porter Overt Hostility Scale ($\alpha = .72$) that measured how often parents openly argue, display physical and verbal hostility, and criticize each other in the presence of their children (Johnson & O'Leary, 1987; Porter & O'Leary, 1980). Exposure to *Negative/Anger Expressiveness* in the family was assessed using both the Family Expressiveness Questionnaire (FAQ; Halberstadt, 1986) and the Anger Expression Inventory (AEI; Spielberger, 1988). The FAQ consists of a 10-item negative dominant subscale ($\alpha = .83$), measuring the frequency of overt anger, contempt, and hostility among family members, and a 10-item negative subdominant subscale ($\alpha = .75$), measuring the frequency of passive sulking, crying, and disappointment among family members. The two FAQ subscales were averaged ($r = .55$, $p < .001$) to yield one measure of negative family expressiveness. The total AEI score was calculated using three 8-item subscales that assessed parents' tendency to express overtly towards other people ($\alpha = .69$), hold angry feelings inside ($\alpha = .68$), and control the experience and expression of anger ($\alpha = .74$). The overall scores based on FAQ and AEI were standardized and averaged ($r = .47$, $p < .001$) into one indicator of exposure to negative/anger expressiveness. *Maternal Depression* was assessed with a 20-item Center for Epidemiological Studies Depression Scale (CES–D; $\alpha = .81$; Radloff, 1977). *Harsh and Restrictive Parenting* was assessed using a questionnaire version of Child-Rearing Practice Report

(CRPR; Block, 1965). The 18-item scale ($\alpha = .83$) was based on previous studies (Deković, Janssens, & Gerris, 1991; Rickel & Biasatti, 1982). Descriptive statistics for adversity measures are shown in Table 1. As we were interested in capturing children's overall exposure to family adversity, the six indices of adversity were standardized and composited into one adversity index. Although a few adversity measures included positive items, which provided some assessment of positive family environment (e.g., financial security, parental affection, parent who is happy, has time to relax, shows patience, and controls anger), it is important to note that, low levels of adversity on this measure do not necessarily indicate a supportive family environment.

Adaptive functioning. Adaptive functioning was assessed during the fall and spring of the kindergarten year using parent-, teacher-, and child-reported measures. For the purposes of this study, we focused on four developmentally salient domains—externalizing symptoms, prosocial behaviors, school engagement, and academic competence—which are described in more detail next. Parent and teacher perceptions of the child's behaviors and skills across these domains were assessed using The MacArthur Health and Behavior Questionnaire (HBQ; Armstrong, Goldstein, & the MacArthur Working Group on Outcome Assessment, 2003). Parent and teacher forms of the HBQ contain parallel scales, described in detail next. Children's perceptions of their own behavior and skills across four domains were assessed using the Berkeley Puppet Interview, which is designed to elicit children's responses to statements that parallel the parent and teacher HBQ scales (BPI; Ablow, Measelle, & the MacArthur Working Group on Outcome Assessment, 2003). The BPI combines both structured and clinical interviewing techniques and allows young children to respond either verbally or nonverbally to opposing statements issued by two puppets about their behavior. Interviewers were extensively trained to probe for more information, to deal with unclear, inaudible, indecisive, or alternate responses, and to create a comfortable, engaging, and interactive environment. Videotaped responses were coded using a 7-point scale based on the statement the child chose to endorse and the degree of endorsement. Interclass correlation coefficients (ICC) were calculated based on 35% of double-coded fall BPIs (ICC range = .91–.98) and 29% of double-coded spring BPIs (ICC range = .92–.99), indicating excellent interrater reliability. Individual items were averaged into subscales and scales according to the BPI manual. The validity and reliability of HBQ and BPI measures have been tested with children ages 5–6, and all three measures show good measurement properties (for details see Ablow et al., 2003; Armstrong et al., 2003).

All three measures contained the same scales. *Externalizing Symptoms* were assessed using an Oppositional Defiant scale (e.g., argues, angry, resentful, misbehaves), Conduct Problem scale (e.g., lies, vandalizes, threatens, cheats), and an Overt Hostility scale (e.g., teases, fights, kicks, taunts). Preliminary analyses revealed that indices of stress reactivity were related differently to a fourth Relational Aggression scale in comparison to the other three scales of externalizing symptoms. We believe that this finding deserves further investigation outside the scope of this study; we thus omitted the Relational Aggression scale from our measure of Externalizing Symptoms. *Prosocial Behaviors* were assessed using a scale measuring the child's predisposition to help others, share, invite bystanders to play, and be considerate, collaborative, fair and empathic. *School Engagement* was assessed using a scale measuring the extent to which the child was excited, eager, happy, frustrated, bored, or irritable about school. *Academic Competence* was assessed with a scale indexing the child's achievement, innate ability, and difficulties in literacy and math, as well as the child's overall academic performance in the classroom in comparison to other classmates. The sample's descriptive and reliability statistics for scales and domains across three informants and two time periods are presented in Table 2.

Using HBQ and BPI data, we conducted eight principal component analyses (PCA) to obtain multi-informant indices of externalizing symptoms, prosocial behaviors, school engagement, and academic competence, separately for the fall and spring assessments. We used a procedure described by Kraemer et al. (2003) for integrating data from multiple informants by triangulating three potentially orthogonal sources of information (i.e., parent, teacher, child). Following this approach, we used parent, teacher, and child report to extract three components for each PCA that conceptually correspond to the following dimensions: (a) trait (i.e., individual differences in adaptation), (b) perspective (i.e., informant characteristics that influence the assessment of the trait), and (c) context (i.e., environmental features that influences expression of the trait). For the purposes of this study, we used only factor scores based on the "trait" component, which weighs each source of information in

the same direction, as an overall core measure of each adaptive domain. Thus, each adaptive domain (e.g., externalizing) is measured by standardized factor scores that represent the common variance across three reports of the domain and are largely free of informant and contextual effects. Table 2 shows PCA loadings for the first (trait) component of each adaptation domain in fall and spring.

Data Preparation and Analytic Procedures

Missing data for the six adversity components, the BPI and HBQ scales, pre- and postprotocol cortisol values, and RSA values to the four challenge and four control tasks were handled using the recommended maximum-likelihood estimation procedure for missing data, specifically, the expectation-maximization (EM) algorithm (Schafer & Graham, 2002). Percentages of missing data were as follows: fall teacher report (0.0%), fall child report (0.9%–1.5%), fall parent report (13.3%–13.9%), spring teacher report (3.0%), spring child report (3.6%–4.4%), spring parent report (16.9%–17.5%), adversity components (11.8%–13.0%), RSA values (3.6%–4.7%), and cortisol values (7.7%–9.8%). Extreme values on standardized final composites were truncated to −3.50 or 3.50 standardized values. All analyses were conducted using the SPSS 15.0 program (SPSS, Chicago). All hierarchical multiple regression analyses were conducted controlling for the child's sex and age at kindergarten entry.

Results

Bivariate Correlations

Bivariate correlations among key variables included in this study are presented in Table 3. Age at kindergarten entry was not related to indices of stress reactivity, adversity, or adaptation, and thus was not included in further analyses. Boys in

this sample were older than girls, experienced higher levels of adversity, and showed poorer adaptation across all domains. RSA reactivity was significantly related only to fall externalizing, with low reactive children exhibiting higher levels of symptoms. Cortisol reactivity was significantly related to fall externalizing symptoms and to both fall and spring school engagement, with high-reactive children exhibiting higher levels of symptoms and lower levels of engagement. Adversity exposure was related to higher externalizing symptoms and lower school engagement across both time points, as well as to lower prosocial behaviors in spring. Lastly, all domains of adaptation showed significant within-time correlations with other domains, as well as significant longitudinal stability from fall to spring.

Regression Analyses

The main goal of the regression analyses was to examine the interactive effects of adversity and stress reactivity on indices of adaptive functioning. While we also tested the main effects of family adversity and stress reactivity on adaptation, these direct effects can only be interpreted in the context of the significant interactive effects that qualify them. For each measure of stress reactivity (i.e., RSA and cortisol), two sets of regression analyses were conducted to predict (a) concurrent fall adaptation and (b) longitudinal change in adaptation by predicting spring adaptation while controlling for fall adaptation. Interactive effects were tested following the procedure outlined by Baron and Kenny (1986). Significant interactions were further investigated using the simple slopes technique proposed by Aiken and West (1991) by comparing the effect of high (i.e., 1 *SD* above the mean) and low (i.e., 1 *SD* below the mean) adversity in children with high and low stress reactivity. High RSA reactivity (i.e., vagal withdrawal) was defined as 1 *SD* below the mean, while low RSA reactivity was defined as 1 *SD* above the mean. In contrast, high cortisol reactivity was defined as 1 *SD* above the mean, and low cortisol reactivity was defined as 1 *SD* below the mean. Finally, we examined whether these main and interactive effects varied for boys and girls.

RSA reactivity. Results of regression analyses examining the effects of RSA reactivity and adversity on adaptation are presented in Table 4. Compared to boys, girls showed better adaptive functioning across all four domains in fall, as well as a decrease in externalizing symptoms and increase in prosocial behaviors across the 1st year of kindergarten. Lower RSA reactivity, as indexed by positive RSA residual values, significantly predicted higher levels of externalizing in fall. Higher adversity exposure predicted higher levels of externalizing and lower school engagement in fall. In addition, adversity exposure predicted an increase in externalizing symptoms as well as a decrease in

*$p < .05$. **$p < .01$. ***$p < .001$.

prosocial behavior and school engagement from fall to spring. However, these main effects were qualified by significant interactions.

The interaction effect between RSA reactivity and adversity significantly predicted fall adaptation across three of four domains: externalizing symptoms, prosocial behaviors, and school engagement. Examination of simple slopes revealed that the effect of adversity exposure on adaptation varied across different levels of RSA reactivity. A stronger relation between adversity and externalizing symptoms was found for children with high RSA reactivity ($b = .35$, $p < .001$) than for those with low RSA reactivity ($b = .15$, $p < .05$). In the context of high adversity, both low- and high-reactivity groups showed elevated externalizing symptom levels, whereas in the context of low adversity exposure, high-reactive children had lower levels of symptoms than low reactive children (see Figure 1). Similarly, adversity exposure was significantly related to prosocial behavior in high-reactive children ($b = -.16$, $p < .05$) but not in low-reactive children ($b = .05$, $p > .05$). However, contrary to findings for externalizing symptoms, high-reactive children showed lower levels of prosocial behaviors than low-reactive children in the context of high adversity but did not differ in the context of low adversity (see Figure 2). Finally, adversity exposure was significantly related to fall school engagement in high-reactive children ($b = -.33$, $p < .001$) but not in low-reactive children ($b = -.12$, $p > .05$). In comparison to low-reactive peers, high-reactive children showed lower levels of fall school engagement in the context of high adversity but higher levels of school engagement in the context of low adversity (see Figure 3). High reactivity thus operated as a risk factor under conditions of high adversity but as a promotive, engagement-enhancing factor in circumstances of low adversity.

Although the interaction between RSA reactivity and adversity exposure did not predict fall levels of academic competence, it did predict change in academic competence from fall to spring. Analyses of simple slopes revealed that exposure to adversity was related to an increase in academic competence in low-reactive children ($b = .12$, $p < .05$) but to a

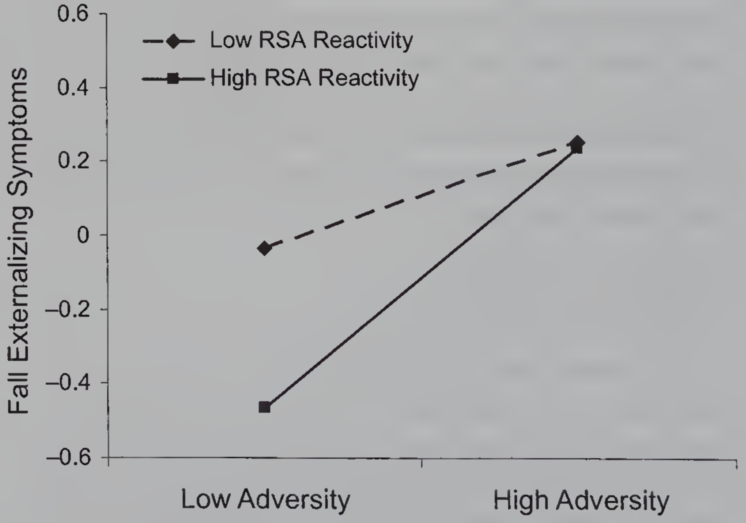

Figure 1. Fall externalizing symptoms as a function of adversity exposure and RSA reactivity.

decrease in academic competence in high-reactive children ($b = -.12$, $p < .05$). In the context of high adversity, low-reactive children showed higher levels of improvement in academic competence than high-reactive children (see Figure 4). However, in the context of low adversity, the reverse was true, with high-reactive children showing higher levels of improvement in academic competence than their low-reactive peers.

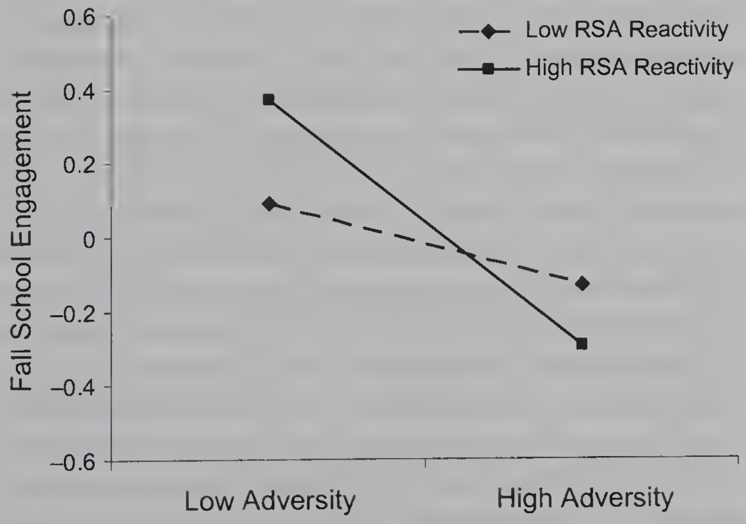

Figure 3. Fall school engagement as a function of adversity exposure and RSA reactivity.
Note. Low and high adversity values are graphed at 1 *SD* below and above the mean, respectively, whereas low and high RSA reactivity are graphed at 1 *SD* above and below the residual score mean, respectively. RSA = respiratory sinus arrhythmia.

The interaction effects of reactivity and adversity on different domains of adaptation did not vary across children's sex, as the three-way interaction effects between sex, reactivity, and adversity were not significant (see Table 4). However, a significant two-way interaction revealed that the main effect of RSA reactivity on 6-month change in academic competence varied for boys and girls. The test of simple slopes indicated a crossover effect such that high reactivity was related to academic improvement in boys ($b = -.06$, $p > .05$), whereas low reactivity was related to academic improvement in girls ($b = .10$, $p > .05$); however, neither slope reached statistical significance.

Cortisol reactivity. Results of regression analyses examining the effects of RSA reactivity and adversity on adaptation are presented in Table 5. High cortisol reactivity significantly predicted higher levels of externalizing and lower levels of school engagement and academic competence in fall. Adversity effects were the same as in regression analyses focused on RSA reactivity. However, these main effects are qualified by the significant interactions.

The interaction between cortisol reactivity and adversity significantly predicted fall prosocial behavior. According to tests of simple slopes, adversity exposure was significantly related to fall prosocial behaviors for high-reactive children ($b = -.16$, $p < .05$) but not in low-reactive children ($b = .06$, $p > .05$). In comparison to low-reactive peers, high-reactive children showed lower levels

of fall prosocial behavior in the context of high adversity but in the context of low adversity showed slightly higher levels of prosocial behavior (see Figure 5).

The interaction effect of cortisol reactivity and adversity did not vary across children's sex, as indicated by nonsignificant three-way interactions (see Table 5). However, significant two-way interactions between sex and adversity emerged for fall school engagement and change in externalizing from fall to spring. Tests of simple slopes indicate that adversity exposure was significantly related to lower school engagement in boys ($b = .34$, $p < .001$) but not in girls ($b = -.13$, $p > .05$). Likewise, adversity exposure was related to an increase in externalizing symptoms in boys ($b = .16$, $p < .01$) but not in girls ($b = .01$, $p > .05$). In addition, the main effect of cortisol reactivity on fall externalizing differed for boys and girls, as indicated by a significant two-way interaction between reactivity and sex in Table 5. Cortisol reactivity was related to higher levels of externalizing in boys ($b = .31$, $p < .001$) but not in girls ($b = .03$, $p > .05$).

Note. Low and high adversity and cortisol reactivity values are graphed at 1 *SD* below and above the mean, respectively.

Discussion

The main goal of this study was to examine how stress reactivity and family adversity influence socioemotional behavior and school readiness skills in children attending kindergarten. Several significant main effects emerged. Consistent with the broad literature on the effects of risk and adversity (e.g., Luthar, 2006), family adversity was associated with concurrent externalizing symptoms and lower school engagement, and with increases in externalizing symptoms and decreases in prosocial behaviors and school engagement over the kindergarten year. However, the effect of adversity on fall school engagement and change in externalizing symptoms was significant only for boys. Adversity did not have a main effect on early kindergarten indices of academic competence. This discrepancy with previous research could be due to the fact that the majority of children in this study come from highly educated families, which may support academic success despite adversity exposure.

Low RSA reactivity was associated with higher levels of externalizing symptoms in the fall, corroborating previous findings of low stress reactivity and underarousal in children with externalizing symptoms (Boyce et al., 2001; Calkins et al., 2007; Mezzacappa et al., 1997; Pine et al., 1996; Pine et al., 1998) and the idea that low RSA reactivity is an index of emotional dysregulation and lability (Beauchaine, 2001). On the other hand, high cortisol reactivity was associated with high levels of externalizing behaviors and low levels of school engagement and academic competence. These findings are consistent with studies that have linked elevated cortisol in response to classroom challenges to poor self-regulation, impulsivity, peer rejection, and more solitary, negative behaviors (Dettling et al., 1999; Dettling et al., 2000; Gunnar et al., 1997; Gunnar et al., 2003), and the notion that hyperresponsivity of the HPA axis signals a risk for maladaptation (Gunnar & Vazquez, 2006). However, these main effects and the absence of others in these models should be interpreted with caution, as they were conditioned by significant interactions. For example, the effect of RSA reactivity on change in academic competence significantly varied across sex, with high reactivity being promotive for boys but a risk factor for girls. In addition, high cortisol reactivity was related to higher levels of fall externalizing symptoms only in boys. These findings suggest that children's sex may be an important factor to consider when examining the effects of stress reactivity on adaptation.

The study's most novel and salient findings emerged when adversity and stress reactivity were considered together, as components of interactions between environmental exposures and measures of biological sensitivity. Stress reactivity moderated the negative effect of family adversity across various domains of adaptation. Overall, the findings are consistent with the stress diathesis hypothesis that high-reactive children show worse adaptive functioning in the context of high adversity. Indeed, such children generally evinced the lowest levels of adaptive functioning of the entire study sample.

However, equally reactive children in settings of low adversity showed the highest levels of adaptation, levels even higher than those of their less reactive counterparts. Specifically, in the context of low family adversity, children who showed high RSA reactivity in response to challenges had the lowest levels of externalizing symptoms and the highest levels of prosocial behaviors and school engagement. Although adaptation showed significant stability from fall to spring, high-reactive children showed improvement in academic competence in the context of low adversity and a decline in competence in the context of high adversity, whereas the inverse was true for low reactive children. Similarly, children who showed high cortisol reactivity to the challenge protocol had the highest levels of prosocial behaviors in the context of low adversity. Further, children exhibiting low RSA reactivity in response to challenges were fully or partially buffered against the harmful effects of adversity on externalizing symptoms, prosocial behavior, and school engagement. Likewise, among children who showed low cortisol reactivity, levels of prosocial behaviors did not significantly change across different levels of adversity.

These findings support the biological sensitivity to context theory advanced by Boyce and colleagues (Boyce 2007; Boyce & Ellis, 2005) and the concept of differential susceptibility to environmental influences proposed by Belsky and colleagues (Belsky, 2005; Belsky et al., 2007). This study illustrates that high reactivity is not merely a pathogenic, risk-amplifying response to adversity but can also promote adaptive functioning. Corroborating Boyce and colleagues' theoretical perspective, children exhibiting high levels of biological sensitivity to context, as indexed by high autonomic and adrenocortical reactivity, were more susceptible to environmental influences in the context of both low and high family adversity. Thus, biologically sensitive children showed the highest levels of symptoms in the context of high family adversity but the highest levels of competence in the context of low family adversity. However, a lack of family adversity does not necessarily imply the presence of a nurturing family environment. Thus, future studies will need to further examine the role of heightened biological sensitivity to context across both stressful, health-undermining and supportive, health-enhancing contexts.

Together, these findings provide strong support for reframing stress reactivity as a biological sensitivity to context. First, the findings are relatively robust, especially for RSA reactivity, which emerged as a significant moderator of adversity effects across all four domains of adaptation. The evidence was parallel, though less robust, for cortisol reactivity, as the interaction effect was significant only for one domain. Second, each observed interaction was consistent with the biological sensitivity to context theory; high reactivity was promotive in the context of low adversity but a risk factor in the context of high adversity. Third, the interaction effect was found for both positive and negative indices of adaptation. Past studies have rarely examined how interactive processes apply to multiple domains of functioning and have often focused primarily on measures of psychopathology. Fourth, these highly consistent interaction effects were found in a normative, community sample of typically developing children. If stress reactivity moderated the effects of adversity on development in a community sample of children, who on average do not face extreme disadvantage or show clinical levels of problem behavior, the interactive effects are likely to be larger at the extreme ends of such distributions.

Finally, the reported interaction effects complement recent work examining individual differences in markers of behavioral and genetic susceptibility to environmental influences. The current findings are consistent with research on behavioral reactivity indicating that children with high levels of negative affectivity are particularly susceptible to both negative and positive experiences (Belsky, 2005; Belsky et al., 2007; Klein Velderman et al., 2006). In addition, the current findings parallel recent research showing that genetic polymorphisms can moderate the effects on adaptive functioning of family adversity, unresolved trauma, or abusive parenting (Bakermans-Kranenburg & van IJzendoorn, 2007; Caspi et al., 2002; Taylor et al., 2006; van IJzendoorn & Bakermans-Kranenburg, 2006) and resonate with the observations of Rutter and colleagues on the previously overlooked protective effects of "risk-engendering" genetic variants (Rutter, Moffitt, & Caspi, 2006). Future studies should examine whether these behavioral, physiological, and genetic markers of susceptibility to contextual factors represent the same phenomena expressed at different levels of assessment or whether they represent different types of susceptibility that may have a cumulative effect on development.

For the purposes of future studies, it is important to note that the nature of the reported interaction effects may depend on several dimensions depicted in the conceptual model of Figure 6. Single studies may be capable of capturing only a portion of the underlying, paradigmatic interaction shown in Figure 6, as the "observational window" shifts from study to study depending on sampling characteristics, the outcomes of the interest, the measure of reactivity, and the type of challenge. For example, the observational window may shift to the right in studies of highly disadvantaged child populations or upward in studies of children with severe behavior problems. Similarly, the slopes of the two component lines may be determined by the researchers' ability to capture the full range of stress reactivity responses and thus distinguish between high- and low-reactive children. It is critical, therefore, that developmental researchers examine and compare the interactive effects of stress reactivity and context across a range of outcomes and environmental influences and that the full scope of existing literature be taken into account in the interpretation of such effects.

The relations between stress reactivity and context are also likely to be dynamic and evolving over time and the present study provides only a snapshot into a potentially complex cycle of bidirectional and reverberatory influences. Boyce and colleagues (Boyce, 2006, 2007; Boyce et al., 2005) have argued, for example, that stress reactivity may not only moderate effects of early experience but may itself *be influenced by* the quality and character of early experience. While our analyses addressed stress reactivity as a moderator of adversity, given the developmental stage of the participants and the nature of the study data, we are mindful that adversity exposure could also play a role in shaping individuals' stress reactivity. From the perspective of evolutionary biology (Ellis, Jackson, & Boyce, 2006), children growing up in supportive and nurturing families might be expected to develop high levels of biological sensitivity to context in order to take greater advantage of the positive and stimulating features of their environments. As a result of both high sensitivity and protective environments, these children would show high levels of competence and low rates of mental and health problems. On the other hand, children

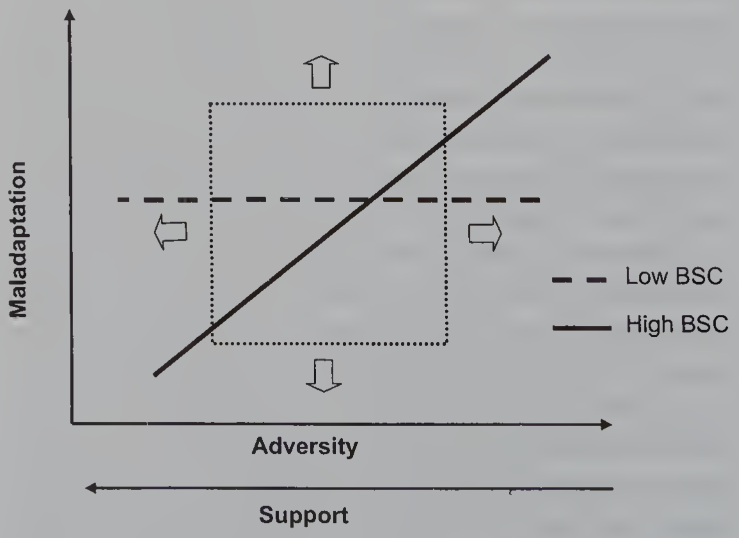

Figure 6. Conceptual model of the interactive effects between biological sensitivity to context (BSC) and environmental influences.

exposed to high levels of early risk and adversity may also develop high biological sensitivity to context, as a means of sustaining vigilance for environmental threats and hazards. Although such vigilance may be adaptive in the short run, over a longer period of time it could augment children's vulnerability to the deleterious effects of adversity. It is not surprising, then, that these children tend to have higher rates of mental and health problems. On the other hand, children who develop low biological sensitivity to context seem to be less affected by both positive and negative environmental influences. These children may consequently demonstrate resilience—adaptation that is better than expected given their adversity exposures—or vulnerability—low levels of adaptation despite growing up in environments abundant with resources and support (Luthar, 2006; Masten & Obradović, 2006). Future studies are needed to examine the processes by which early experiences shape children's biological stress responses.

Strengths, Limitations, and Future Directions

This study had several unique strengths as well as notable limitations that highlight important directions for future improvements. First, the study was based on a large, ethnically diverse sample of kindergarten children; however, a majority of children came from families with relatively high socioeconomic status, as indicated by income and parents' education. Second, the study was unique in that it employed a carefully controlled measure of autonomic reactivity that took into account the possible effects of motor activity and engagement demands elicited by challenge tasks. However, only one third of the sample had elevated cortisol in response to stress reactivity protocol, which may have contributed to less robust findings for cortisol reactivity. Future studies should attempt to raise the responder rate, as a lack of response to the current protocol does not necessarily indicate a low reactivity to more intense, real-life stressors. Third, we included the various sources of family adversity as an index of early experience. However, future researchers should explicitly assess positive environmental influences in children's lives by including measures of social support and resources. Another strength of the current study was the use of multiple informants. While it may not always be feasible to use multiple informants when assessing family adversity, given the young age of the participants and the nature of the construct, future studies should, where possible, triangulate the child, parent, and teacher reports of adaptation, thus minimizing informant variance. Fourth, the study was unique in its effort to compare how both indices of autonomic and adrenocortical reactivity interact with early family adversity to predict adaptation. In addition to examining how indices of different types of stress reactivity affect children's behaviors and skills, future research should examine how different stress response systems interact to produce unique stress reactivity profiles, which may be related to different adaptive patterns across adversity exposure. As discussed earlier, researchers might use person-focused analytic approaches to examine whether the same children express analogous behavioral, physiological, and genetic sensitivity to contextual factors. Finally, future research should examine transactional relations between stress reactivity and adversity across longer periods of development, as adaptation in this study showed high stability over the 6-month period.

Conclusion

Given the pervasive and long-lasting effects that adversity can have on adaptation (Luthar, 2006; Obradović et al., in press; Sameroff, 2006), it is important to elucidate the processes that buffer or exacerbate these effects. This study represents a rare attempt to examine complex interactions between biological and environmental factors. The findings indicate that children's biological sensitivity to social context played an important role in moderating the effects of early experiences of family adversity on positive and negative indices of adaptive functioning. We believe that studies such as the one reported here can advance future prevention and intervention efforts, to address more holistically the social disparities in children's competence and psychopathology.

This study examined relations among family environment, cortisol response, and behavior in the context of a randomized controlled trial with 92 children ($M = 48$ months) at risk for antisocial behavior. Previously, researchers reported an intervention effect on cortisol response in anticipation of a social challenge. The current study examined whether changes in cortisol response were related to later child aggression. Among lower warmth families, the intervention effect on aggression was largely mediated by the intervention effect on cortisol response. Although the intervention also resulted in significant benefits on child engaging behavior, cortisol response did not mediate this effect. These findings demonstrate meaningful associations between cortisol response and aggression among children at familial risk for antisocial behavior.

The way in which children respond to stress is an important aspect of development. Although experimental studies with animals have led to influential theoretical modeling of the role of human cortisol regulation in maladaptive outcomes (Champagne & Meaney, 2006; Francis, Caldji, Champagne, Plotsky, & Meaney, 1999; Levine, 1957; Liu et al., 1997; Meaney, 2001), only limited experimental work has been done with humans. In children, cross-sectional studies largely support a negative relation between cortisol response to a stressor and aggressive behavior (Blair, Granger, & Razza, 2005; Snoek, Van Goozen, Matthys, Buitelaar, & Van Engeland, 2004; van Goozen, Matthys, Cohen-Kettenis, Buitelaar, & van Engeland, 2000; van Goozen et al., 1998), although the exact nature of the relation has yet to be established (Dadds & Rhodes, 2008; Hart, Burock, London, Atkins, & Bonilla-Santiago, 2005; Rutter, 2008).

A rich literature demonstrates a relation between a blunted child cortisol response to stress and unresponsive or neglectful environments (Gunnar, Fisher, & the Early Experience, Stress and Prevention Network, 2006). However, as with the cortisol–behavior association, the nature of these cortisol–context relations is not well understood.

One model of the development of an abnormal stress response (e.g., Caldji, Diorio, & Meaney, 2000; Liu et al., 1997) suggests that mothers living under stressful conditions display abnormal stress responses, which may be transmitted directly to their offspring. Such maladaptive stress responsivity may lead to various negative outcomes, including aggression. Other models emphasize the complex manner in which genes and environment shape physiology and behavior through Gene × Environment interactions and Gene × Environment correlations (Rutter, Moffitt, & Caspi, 2006). For example, genes that shape maternal stress response could impact the environment by influencing

parenting behavior, which, in turn, influences maternal–child interactions. This Gene × Environment effect could subsequently impact child stress response, which, in turn, may influence child behavior. From this perspective, relations among parent cortisol, parent behavior, child cortisol, and child behavior could each reflect the influence of both genes and the environment shared by parents and their offspring.

Experimental approaches provide unique opportunities to examine relations among family environment, child physiology, and behavior. The current study takes advantage of a randomized controlled prevention trial of an early family intervention among children at high risk for antisocial behavior. Previously, Brotman and colleagues demonstrated that the intervention impacts three aspects of parenting (responsive parenting, harsh parenting, and stimulation for learning), child engaging behaviors with unfamiliar peers, and child aggression (Brotman et al., 2005; Brotman et al., 2008), and that intervention effects on parenting are meaningfully related to the prevention of aggression during parent–child interactions (Brotman et al., 2009). Furthermore, the behavioral family intervention resulted in changes in children's cortisol response in anticipation of a social challenge with unfamiliar peers (Brotman et al., 2007), demonstrating the malleability of the stress response system among children at high risk for antisocial behavior. These reports did not examine how the family environment relates to child stress response or the relations between child cortisol and aggressive behavior. The primary aim of this study is to examine if intervention effects on child cortisol are meaningfully related to later child aggressive behavior, observed during a parent–child interaction 16 months after the intervention. To explore the specificity of this relation, the study also examines intervention effects on child engaging behavior during the same parent–child interaction and whether changes in cortisol mediate any observed intervention effects.

Cortisol Response and Behavior

Stress regulation is implicated in the development of psychopathology (e.g., Alink et al., 2008). Cortisol response to a stressor has been identified as an important indicator of stress regulation, with consequences for child behavior. However, as noted above, considerable literature demonstrates the complex nature of associations among cortisol, context, and behavior. Although low cortisol reactivity to a stressor (i.e., hypocortisolism) has been linked to aggressive behavior (Gunnar & Vazquez, 2001), careful analysis demonstrates more complex associations. For example, unique subgroups of children may exhibit positive associations between cortisol responding and aggression (e.g., Dadds & Rhodes, 2008; Hart et al., 2005; Rutter, 2008). Cortisol does not exhibit a simple one-to-one correspondence with aggression but, rather, can show positive associations in some contexts and negative associations in others. Theories explaining the process in which cortisol is linked to aggression differ. The fearlessness theory (Raine, 1993) posits that low levels of cortisol arousal or reactivity lead children to be fearless, and such fearless children are more likely to initiate fights because they are not concerned about consequences. Stimulation seeking theory (Zuckerman, 1979) argues that some children experience a low arousal, negative state, which leads them to seek higher levels of arousal via aggressive behavior. A third theory proposes that insensitivity to social and emotional distress signals (e.g., fear) in peers predisposes children to certain types of aggression (Blair, 2003).

Relative to typically developing children, children at high risk for psychopathology (e.g., children with familial antisocial behavior, maltreated children, or those raised in orphanages) or those with clinical diagnoses of disruptive psychopathology exhibit low or flattened cortisol responses to challenging situations as well as to circadian changes (Fisher, Gunnar, Chamberlain, & Reid, 2000; Gunnar & Vazquez, 2001; Hart, Gunnar, & Cicchetti, 1995). Considerable empirical literature relates low cortisol reactivity to aggression and disruptive psychopathology (Snoek et al., 2004; van Goozen et al., 1998; van Goozen et al., 2000). This literature, summarized in a recent meta-analysis, finds a medium effect size ($d = .57$) of low cortisol stress response for children characterized as antisocial or with clinical diagnoses of conduct disorder or oppositional defiant disorder (van Goozen, Fairchild, Snoek, & Harold, 2007). Although preschoolers were not included in the meta-analytic study, a study by Blair et al. (2005) found a similar relation between highly aggressive behavior and blunted cortisol reactivity among preschoolers from low-income families.

Despite the findings from one meta-analysis (van Goozen et al., 2007), some empirical evidence suggests either no significant relation between cortisol reactivity and aggression (see meta-analysis by Alink et al., 2008) or even a positive relation of cortisol reactivity to aggression (e.g., Hart et al., 2005). This lack of a simple one-to-one correspondence between stress response and aggression may be due to multiple complicating factors, including child age and type of disruptive psychopathology (Alink et al., 2008; Dadds & Rhodes, 2008). For example, children who exhibit physical aggression that is predatory or instrumental may be more likely to have blunted cortisol responses to stress than children with reactive aggression or those with more general nonaggressive disruptive psychopathology (Dadds & Rhodes, 2008; Loney, Butler, Lima, Counts, & Eckel, 2006; McBurnett, King, & Scarpa, 2003). The current study examines observed child behavior (physical aggression and socially engaging behavior) during a standardized parent–child interaction paradigm and cortisol levels in response to a social challenge among a relatively homogenous age group of children (33–63 months) followed prospectively over a 24-month period.

Experimental Studies of Child Neurobiology and Behavior

Because the literature on the stress response and aggressive behavior in humans is largely based on cross-sectional studies, there have been few advances in understanding the causal relations between cortisol response and child aggression. As a result, a call has been made for greater use of experimental studies that can illuminate causal mechanisms underlying the link between neurobiology and behavior (Rutter, 2008; Tremblay, 2008). Experimental studies of interventions that alter both the stress response and child behavior provide unique opportunities to examine the nature of the relation between cortisol response and behavior. In theory, restoring a high-risk child's physiological stress reaction to a typical, reactive state may lead to improved emotional and cognitive appraisal of a socially stressful situation, thus facilitating a less aggressive reaction and a potentially more positive, socially engaged reaction to stressful events (van Goozen et al., 2007).

Two experimental studies with maltreated children report changes in cortisol and child behavior (Dozier, Peloso, Lewis, Laurenceau, & Levine, 2008; Fisher, Stoolmiller, Gunnar, & Burraston, 2007). These studies considered diurnal patterns of cortisol secretion during typical days and did not examine the link between cortisol levels in response to stress and child behavior. A third study of older children (aged 8–13) with behavior disorders found that pretreatment cortisol response to stress moderated intervention outcomes on conduct problems (van de Wiel, van Goozen, Matthys, Snoek, & van Engeland, 2004). Since this study did not examine intervention effects on cortisol, the consequences of child stress response on child behavior remains unknown. In a prior report of immediate intervention outcomes on cortisol response in the current study sample, Brotman and colleagues found that intervention effects on cortisol levels in anticipation of a social challenge and engaged behavior with peers during the challenge were not related (Brotman et al., 2007). The current study extends this work and other prior experimental studies in this area by examining the links between immediate intervention effects on child cortisol response and longer term intervention effects on child engaging and aggressive behavior with the parent, with consideration of the family environment.

Early Family Environment and Stress Neurobiology

Stress-sensitive neurobiology is shaped by early experience, especially by caregiving (Gunnar & Quevedo, 2007). Family environmental factors that operate at key points in development might sculpt hypothalamic–pituitary–adrenal (HPA) axis regulation in children, much as environmental factors have been shown to play a role in HPA regulation in rodents and nonhuman primates (e.g., Caldji et al., 2000; Levine, 1957; Liu et al., 1997). Animal studies suggest both genetic and environmental factors involved in the transmission of abnormal stress regulation. Offspring at high risk for abnormal neuroendocrine stress regulation are characterized by having lower warmth parents (Meaney, 2001). Studies in young human children find evidence of parallel processes (Fisher, Gunnar, Dozier, Bruce, & Pears, 2006; Gunnar et al., 2006; Hane & Fox, 2006). Children from high-risk, stressful environments exhibit lower or flat diurnal cortisol levels compared to nonstressed children ("hypocortisolism"; Gunnar & Vazquez, 2001; Hart et al., 1995; Heim, Ehlert, & Hellhammer, 2000; Hertsgaard, Gunnar, Erickson, & Nachmias, 1995; Nachmias, Gunnar, Mangelsdorf, Parritz, & Buss, 1996). Although both positive and negative relations between quality of caregiving and child cortisol response to stress have been found among low-risk families (Blair & Diamond, 2008; Gunnar, Brodersen, Nachmias, Buss, & Rigatuso, 1996; Gunnar & Vazquez, 2001; Hane & Fox, 2006; Nachmias et al., 1996), studies of high-risk families consistently link suboptimal caregiving with low child cortisol response. For high-risk families, responsive parenting may serve as an important moderating risk or buffering factor for the development of hypocortisolism (i.e., low cortisol levels; Fisher et al., 2006; Gunnar & Vazquez, 2001).

In addition to the responsive nature of the caregiving environment, a small literature in humans suggests that parent stress responding and depression may be related to child cortisol response to stress in early childhood. A large twin study found modest similarity in afternoon basal cortisol levels between parents and children (Schreiber et al., 2006). A small study of diurnal levels of cortisol in typically developing children and their parents documented a positive correlation between diurnal levels of parent and child cortisol (Young, Vazquez, Jiang, & Pfeffer, 2006). Another study of low-risk families found a positive correlation between infant and mother diurnal cortisol, but the correlation was not significant between child and mother cortisol reactivity during a separation paradigm (Thompson & Trevathan, 2008).

Related to parent psychopathology, a small literature suggests that parent depression during early childhood may be related to child cortisol patterns (e.g., Lupien, King, Meaney, & McEwen, 2000). Parent depression in the first 2 years of life was found to predict child cortisol reactivity to a stressor at age 7 (Ashman, Dawson, Panagiotides, Yamada, & Wilkinson, 2002). In sum, parental warmth, parent stress response, and parent depression are likely to influence child cortisol response in early childhood. Yet, the aforementioned studies have not systematically characterized the family environment or examined parent and child factors among children from high-risk stressful environments. In the current study, therefore, we consider three aspects of the family environment (i.e., parental warmth, stress response, and depression) in relation to children's cortisol and behavior in a high-risk sample.

The Current Study

The current study takes advantage of a randomized controlled trial of an early family intervention among preschoolers at familial risk for antisocial behavior. In a series of studies, the intervention has been found to promote responsive parenting and child engaging behavior with peers, reduce physical aggression during parent–child interactions, and alter cortisol response in anticipation of a social challenge with peers (Brotman et al., 2005; Brotman et al., 2007; Brotman et al., 2008). Guided by current models of developmental psychopathology, we evaluate whether increased cortisol response is related to intervention effects on aggressive behavior with parents. To yield a more complete picture and to evaluate the specificity of the cortisol–aggression connection, we will also evaluate relations among cortisol response and engaging behavior with parents.

Method

Participants

This study includes children and parents who participated in a randomized controlled trial of a family intervention aimed at preventing early conduct problems and later antisocial behavior. The trial methodology and characteristics of participants are detailed elsewhere (Brotman, Gouley, O'Neal, & Klein, 2004; Brotman et al., 2005; Brotman et al., 2008). Briefly, all family court records of youths under the age of 16 adjudicated in two boroughs in New York City were screened between 1997 and 2001 for the presence of preschool-age siblings. "Sibling" was defined as a child who was biologically related to, or lived with, the adjudicated youth for at least 1 year, and whose caregiver also raised the adjudicated youth. Families were eligible if siblings were between 33 and 63 months, the caregiver spoke English, and the family lived within the designated geographic area. Families were ineligible if caregivers had a current substance use or psychotic disorder determined by structured diagnostic interview, or if preschoolers had pervasive developmental disorders or severe or profound mental retardation as reported by parents or indicated by standardized cognitive testing. Forty-eight percent of eligible families (*N* = 92) agreed to participate and completed assessments. Seven of the 92 families had more than one preschool-age child; none of the siblings were included in this study. Forty-seven families were randomized to the intervention condition and 45 families to the control condition that received no intervention.

Sixty-eight percent of preschoolers were biological siblings of the adjudicated youths (12% full; 56% half), 3% adoptive siblings, and 28% biological nephews, nieces, or cousins raised as "siblings." Eighty-three percent of caregivers (parents) were the preschoolers' biological mothers, 2% biological fathers, 10% grandmothers, 3% adoptive mothers, and 2% other female relatives. Parent mean age was 36.3 years (*SD* = 9.2). Forty-five percent of parents had not completed high school and 59% of families had household incomes under $15,000. Fifty-three percent of preschoolers were girls; 65% were African American, 27% Latino, and 8% other or mixed race. Child mean age was 47.52 months (*SD* = 8.28) and the average child IQ score (DAS; Elliott, 1990) was 83.2 (*SD* = 12.9). The stressors experienced by the sample are described elsewhere (Brotman et al., 2004); in addition to socioeconomic disadvantage and sibling antisocial behavior, children were exposed to high rates of maternal psychopathology (based on semistructured diagnostic interviews) and stressful life events (based on maternal reports).

Preventive Intervention

The prevention program was adapted from the Incredible Years Series (IYS), an efficacious program developed and tested extensively by Webster-Stratton (e.g., Webster-Stratton & Hancock, 1998). The program aimed to improve parenting practices and preschoolers' social competence with the goal of preventing later conduct problems. The program consisted of 6–8 months of active intervention (November–June), followed by a 3-month booster intervention (October–December) initiated approximately 4–6 months after the end of the intervention. The active intervention included 22 group sessions for parents, 22 group sessions for preschoolers, 22 guided parent–child interactions, and 10 home visits.

As per published IYS manuals, group leaders coached parents to use specific parenting skills (e.g., labeled *praise, time out*) and modeled, directed, and reinforced appropriate behavioral strategies. The program specifically encourages parents to use nonharsh, consistent, and appropriate disciplinary strategies, be less critical, and use positive reinforcement and play interactions to promote children's social competence. Groups for preschoolers incorporated elements from the Incredible Years Dinosaur Social Skills and Problem-Solving Curriculum (Webster-Stratton, 1990), which has been shown to increase the efficacy of the Parent Program (Webster-Stratton, Reid, & Hammond, 2004). Child group leaders taught social skills, reinforced positive behaviors, and provided consequences for negative behaviors. Home visits were designed to help parents implement skills at home. Leaders from the parent and children's groups together provided home visits following a curriculum corresponding to parent and preschool group lessons. Home visits created opportunities for developing and implementing behavior plans (e.g., placement of a time out chair in a crowded apartment).

The control condition consisted of assessments and monthly phone calls through which family service use and changes to family circumstances were evaluated. Parents were paid $5 for these monthly phone interviews. If families requested assistance with identifying social, educational, or mental health resources during these calls, a clinician followed up with information provided over the telephone.

Assessment Procedures

Participants were assessed four times, 8 months apart, over 24 months: baseline or preintervention (Time 1, Month 0), postintervention (Time 2, Month 8), 8-month follow-up (Time 3, Month 16), and 16-month follow-up (Time 4, Month 24; see Table 1). Previously, we reported main effects of the intervention on child cortisol response immediately postintervention (Brotman et al., 2007), and intervention effects on child aggression during a parent–child interaction at Time 4 (Brotman et al., 2008). The intervention took place between Time 1 and Time 2 and the booster sessions took place between Time 2 and Time 3; no intervention took place between Time 3 and Time 4. The length of time between assessments was not different for intervention and control conditions, $t(77) = -0.42$, $p > .10$. The preintervention assessment required three or four visits, and the three postintervention assessments required two visits each; one visit was at the study center and one was in the home.

Table 1
Timeline of Assessments

Time 1	Time 2	Time 4
0 months	8 months	24 months
4 years old	4 years 8 months old	6 years old
Preintervention (baseline)	Immediate postintervention	16 months postintervention
Child cortisol reactivity	Child cortisol reactivity	Child aggression
Parent cortisol reactivity		Child engaging behavior
Parent depression		
Parent warmth		

Measures

Child cortisol in anticipation of a social challenge. Neuroendocrine functioning was measured by collecting salivary cortisol samples prior to an unfamiliar peer situation (prechallenge cortisol). Cortisol assessments were collected at baseline prior to randomization (Time 1) and repeated in an identical fashion immediately after intervention (Time 2). Samples were collected using a sterile cotton roll held by dental floss. The child mouthed the roll until it was wet. The sample was then placed in a vial and kept in a freezer until transported on ice to the laboratory. Food intake was controlled during the collection process.

The social challenge involved entry into an unfamiliar peer group for 30 min of play at a nursery school several blocks from the study center. Observations were scheduled with the school to correspond with planned free play. Approximately, 40 children (ages 34–60 months) from diverse socioeconomic and ethnic backgrounds were enrolled in the school. During free play, children were free to move from station to station (e.g., blocks, pretend house, art table) in a large room designed for this purpose. At least one teacher and three assistants from the school staffed free play.

Prior to leaving the study office for the school, a research assistant unaware of intervention status and study hypotheses explained to the child (in front of the parent) that he or she was "going to a school to play with some other children." Thus, children were informed about an impending potentially stressful experience prior to cortisol sampling. Two or three research assistants escorted the child and parent to the school (a 10– to 15–min walk). On arrival, and in the presence of the parent, a salivary cortisol sample was collected. The sample was collected approximately 15–20 min after the child was told about the challenge task. Because cortisol release in preschoolers occurs as early as 10 min from the stimulus presentation, we consider this cortisol sample to be an index of the child's *anticipation* of the challenge. After the cortisol sample was taken at the school, the child was then required to separate from the parent and accompanied to the play area by one or two research assistants who observed the child during 30 min of free play. Assessment procedures, including timing of cortisol collection, were identical for intervention and control conditions and for both assessment points. For Times 1 and 2, children's cortisol samples were collected between 10:00 and 11:30 a.m. or between 2:00 and 4:00 p.m., with the majority collected in the afternoon. Although individual children were not assessed at the same exact time at both assessments, major differences in levels based on diurnal patterns are not expected in this time range from late morning to early afternoon. Further details of the observational paradigm and intervention effects on behavior observed during this procedure are presented elsewhere (Brotman, Gouley, & Chesir-Teran, 2005; Brotman et al., 2005).

Children's cortisol levels in anticipation of the social challenge may reflect the child's response to a number of cues including separation from the parent, entry into a social peer situation, or a general transition. To further understand the challenge data, we also collected cortisol samples at home over the course of the day to evaluate diurnal patterns. We examined intervention effects on diurnal patterns but did not find an effect. Details on the diurnal patterns and the relation between cortisol in anticipation of a social challenge and cortisol levels over the course of the day at home are reported in Brotman et al. (2007).

Observed child behavior during parent–child interaction. Child behaviors with the parent were observed by raters unaware of intervention status during semistructured, parent–child interactions at the home and study center at Times 1–4. For this study, we utilize data from Times 1 and 4 only. At each assessment point, two parent–child interaction measures were obtained, a 10-min session at the family's home (5-min child-directed free play and 5-min parent-directed puzzle task), and a 15-min session at the study center (7-min child-directed free play, 5-min parent-directed puzzle task, and 3-min cleanup). Home and center-based assessments took place approximately 1 week apart. Home assessments were coded live and assessments in the study center were videotaped and coded at a later time. Different raters coded home and center-based observations and were uninvolved in other aspects of the study.

The Dyadic Parent–Child Interaction Coding System–Revised (DPICS–R; Robinson & Eyberg, 1981; Webster-Stratton, 1985) was used to record the frequency of discrete aggressive behaviors in both settings. Observed child physical aggression was derived from the two DPICS–R codes of physical aggression: child physical negative (i.e., child is physically aggressive toward parent) and child destructive (i.e., child destroys, damages, or attempts to damage objects). The two codes of physical aggression were significantly related ($r = .43$, $p < .001$) and combined. Reliability estimates consider average reliability across assessment time points. To estimate interrater reliability, approximately 20% of observations (in each setting, at each time point, and in each condition) were coded by two raters. Interrater agreement, calculated via single-measure intraclass correlation coefficients with a one-way random-effects model (Shrout & Fleiss, 1979), was .85 for direct home observations and .84 for videotaped center observations. Mean level aggression scores across home and center settings were not significantly different and were highly correlated ($r = .67$, $p < .001$). At each time point, we created a composite index of physical aggression by combining ratings across the two settings. The total physical aggression score reflects the number of times the child aggressed toward his or her parent or destroyed objects over a total of 25 min. The estimated reliability of the composite across all time points was .88 (Lord & Novick, 1968).

Although the primary focus of this study is on aggressive behavior, we also examined engaging behavior with the parent to gain a more complete picture of behavioral outcomes. Of note, although we have reported immediate intervention effects on engaging behavior with peers (Brotman, Gouley, Chesir-Teran, & Dennis, 2005), we have not previously examined longer term intervention effects (Time 4) on engaging behavior with the parent. The Global Impressions of Parent–Child Interactions (GIPCI; Brotman, 1998) was used to make global ratings of child positive, engaging behavior with the parent. GIPCI ratings were made on a 5-point scale using descriptions of prototypic behaviors. Child positive engagement was the average of the following three GIPCI scales: child emotion (i.e., positive emotional tone of the child behaviors), child play with the parent (i.e., child shares and encourages activity with parent, shows appropriate verbal skills and cooperation), and reverse-coded child disconnection (i.e., child is withdrawn, aimless, requires encouragement to play and relate to parent). The three codes of positive engagement were significantly related ($rs = .53–.69$) and were combined. We combined home and study center observations because both were related ($r = .38$ at Time 1 and $r = .44$ at Time 4). Test–retest reliability for the combined scale ranged from .47 to .61. The ICC for the combined composite is .75. The estimated reliability of the composite was .83 (Lord & Novick, 1968).

Parent warmth. The Home Observation for the Measurement of the Environment–Early Childhood Version (HOME–EC; Caldwell & Bradley, 1984) was used to assess aspects of the home environment and parenting. The observation of the parent–child relationship occurred in the home over the course of an approximately 2-hr visit. For the current study, we used warmth data at Time 1. Items are rated by interviewers as present (1) or absent (0). We employed the conventional Caldwell and Bradley HOME Warmth scale (Caldwell & Bradley, 1984). It is a seven-item scale including the following items: "Parent holds child close 10–15 min per day"; "Parent converses with child at least twice during visit"; "Parent answers child's questions or requests verbally"; "Parent usually responds verbally to child's speech"; "Parent praises child's qualities twice during visit"; "Parent caresses, kisses, or cuddles child during visit"; and "Parent helps child demonstrate some achievement during visit." The summary score was the mean of all seven items. Internal consistency was moderate ($\alpha = .61$). Approximately one third of the sample had scores of 1 on all seven items (i.e., all seven items were observed in the home). For the remainder of the sample (67%), scores ranged from 0 to 6.

Parent depression. We assessed parent depression using the Structured Clinical Interview for DSM–IV nonpatient version (SCID–NP; Williams et al., 1992) by trained clinical psychologists. An independent clinician reviewed all clinical interviews for diagnostic decision making by interviewers. Psychometric properties of the SCID are adequate in other samples (Williams et al., 1992).

Parent cortisol in anticipation of a challenge. Parent neuroendocrine functioning was measured by collecting salivary cortisol samples prior to the administration of a Wechsler Adult Intelligence Scale–Vocabulary subtest and a Wide Range Achievement Test–Reading subtest (i.e., prechallenge cortisol). Cortisol assessments were collected prior to randomization (Time 1) on the same day and within a 1-hr time period of when the child provided his or her sample. Parents were informed that they were going to be asked to complete a test of their vocabulary and reading skills. Saliva samples were taken approximately 10 min after the instructions were given; as such, we consider this cortisol sample to be an index of the parent's *anticipation* of the challenge. The literature supports that cognitive testing should serve as a stressful challenge for adults in a similar fashion as the peer entry paradigm is stressful for young children. A cognitive test may be perceived as especially challenging for parents in this sample since their mean level of cognitive functioning and achievement was well below average (Brotman et al., 2004). Samples were collected using a sterile cotton roll held by dental floss. The parent mouthed the roll until it was wet. The sample was then placed in a vial and kept in a freezer until transported on ice to the laboratory. Food intake was controlled during the collection process. The assessment of parent cortisol was designed so that it would yield information that would be helpful in interpreting child cortisol levels. As with child cortisol, parent cortisol was also collected from parents at home at four time points over the course of the day (the same day and time points as the child). We do not report these data here, but we evaluated these diurnal levels to aid interpretation of challenge data. Diurnal levels are available from the authors.

Analyses

Attrition and imputation strategies. Time 1, 2, and 4 data were utilized for the current study. There was modest attrition by Time 2 (87% retained) and Time 4 (77% retained). There were no differences by intervention status in the percentage of children and parents missing data at any time. Furthermore, there were no baseline differences between those with complete data versus those with missing data at later times, and there were no significant baseline score by intervention status interactions in predicting missingness. Given these results, we assume that the data are missing at random (Schafer & Graham, 2002).

As per Little and Rubin (2002), we used the SAS Multiple Imputation (SAS Institute, Cary, NC) procedure with 10 replicated imputations to impute data for all study variables; the imputation made use of the joint distribution of all available measures of parent and child functioning. Imputations were conducted separately for the control and intervention groups to account for the possibility of different missing data patterns by group (Little & Rubin, 2002). SAS PROC MIANALYZE was used to combine the results of the 10 imputations for the final inference. This combination of multiple imputations provides estimates of standard errors that take into account the fact that some data were imputed. Of note, we did not impute missing data for observed child physical aggression because the distribution of scores was highly skewed, even after log transformation. The imputation methods are optimal for normally distributed variables and are not appropriate for highly skewed variables. Therefore, we used the approach of carrying the last time point forward to replace the missing values for this variable. All analyses yielded highly similar results regardless of using the imputed or nonimputed data set.

Analytic approach. Correlations were estimated and tested to determine the concurrent relations among aspects of the family environment, child cortisol response, and child behavior. We tested a mediation process in which child cortisol response was expected to mediate the intervention effect on later child outcomes (i.e., aggression, engaging behavior): The intervention effect on child cortisol response was expected to be related to the intervention effect on child outcomes. We employed the "joint significance test" strategy in which mediation is inferred if there is evidence that both paths *a* (intervention effect on cortisol) and *b* (change in cortisol and later behavior) in Figure 1 are significant (MacKinnon, Lockwood, Hoffman, West, & Sheets, 2002). We also carried out the conventional Sobel test described by Baron and Kenny to test the significance of the mediation model (1986).

To test the percent of the intervention effect accounted for by the mediator, we used an equation that is appropriate for a nonlinear mediation model. In a linear-based mediation

model, the total intervention effect (c) is equal to the sum of the part that is explained by the mediator (paths a and b) and the part that does not involve the mediator (c'). In a nonlinear mediation model, like our model, c is not equal to the total intervention effect (i.e., c is not equal to the sum of the part explained by the mediator [a and b] and the part that does not explain the mediator [c']; Fleiss, Levin, & Paik, 2003). For this reason, we compute the total effect as the indirect effect/total effect $= (a \times b)/[(a \times b) + c']$.

Poisson regression analysis, a log-linear approach appropriate for low frequency behavior counts with skewed distributions (Fleiss et al., 2003), was used to test the relation between cortisol change and aggression. The Poisson regression model was carried out using a generalized estimating equation approach (Diggle, Heagerty, Liang, & Zeger, 2002; Liang & Zeger, 1986; Zeger, Liang, & Albert, 1988) with a log-link function (Diggle et al., 2002). PROC GENMOD in SAS® (SAS Institute, Cary, NC.) was used to perform the analyses.

A mediation model is ideally tested in a design demonstrating time precedence in which the intervention occurs before the mediator and the mediator occurs before the outcome (Cole & Maxwell, 2003; Kraemer, Wilson, Fairburn, & Agras, 2002; Sobel, 1990). Note that we only examined the outcomes at Time 4, rather than modeling change over multiple time points, due to the temporal limitations of testing a mediation model.

Upon inspection of the distribution of child aggression scores across the range of parental warmth, we found that there was essentially no child aggression at Time 1 or Time 4 among the families with scores of 1 on warmth (33% of the sample). Among the high-warmth families (warmth = 1), only 1 child in the control group and 1 in the intervention group had nonzero scores at baseline. At Time 4, 2 children in the control condition had nonzero aggression scores and all children in the intervention had 0 aggression scores. As a result, we eliminated the families with scores of 1 on warmth from the mediation analyses relating child cortisol to aggression.

Results

Preliminary Analyses

Descriptive means and standard deviations for the sample by intervention are presented in Tables 2 and 3. Because both tables are intended to provide information necessary for interpretation of the mediation analyses on aggression, all descriptive information is presented with the removal of the families with scores of 1 on warmth at baseline. As shown in Table 2, no baseline (Time 1) intervention group differences were found for any of the child or family variables.

Relations Among the Family Environment, Cortisol Response, and Child Behavior

Table 3 shows concurrent, baseline relations among aspects of the family environment (parent cortisol response, warmth, and depression), child cortisol response, and child behavior.

Intervention Effect on Cortisol (Path a)

Previously, Brotman et al. (2007) reported intervention effects on cortisol for the entire sample. Since we removed a subset of families with high

Table 2
Descriptives (Mean and Standard Deviation) by Intervention Status

	Control (N = 24)		Intervention (N = 33)	
	Time 1	Time 2	Time 1	Time 2
Child cortisol	0.07 (0.31)	−0.09 (0.33)	0.07 (0.32)	0.27 (0.50)
Parent cortisol	0.11 (0.27)		0.05 (0.29)	
Parent warmth	0.66 (0.18)		0.67 (0.16)	
Parent depression	42%		35%	
	Time 1	Time 4	Time 1	Time 4
Child aggressive behavior	0.24 (0.79)	1.05 (3.73)	0.86 (2.41)	0.26 (0.71)
Child engaging behavior	3.96 (0.50)	4.02 (0.56)	3.81 (0.38)	3.91 (0.44)

Note. Table does not include families with warmth = 1.

Table 3

Descriptives and Correlations Among Baseline Early Family Environment, Child Cortisol Response, and Child Behavior

	N	*M* (*SD*)	Child cortisol	Parent cortisol	Parent warmth	Parent depression	Child aggression
Child cortisol	44	0.07 (0.31)					
Parent cortisol	47	0.08 (0.28)	.25				
Parent warmth	57	0.66 (0.17)	.08	.21			
Parent depression	56	0.39 (0.49)	−.08	.01	−.14		
Child aggression	57	0.50 (1.69)	−.17	−.07	−.21	−.04	
Child engaging	57	3.90 (0.45)	−.22	.21	.24†	.25†	−.24†

Note. N for correlations in the low warmth group ranged from 40 to 57. Table does not include families with warmth = 1.
$^{\dagger}p < .10$.

warmth scores from the mediation analyses, we first needed to replicate the intervention effect on cortisol among the remaining families. Results indicate that the intervention had a significant effect on cortisol, Estimate (*SE*) = .49 (.20), $p < .05$. Similar to findings previously reported for the full sample, cortisol levels increased in the intervention condition (.07 to .27) and decreased in the control group (.07 to −.09; see Table 2). Even after removing the high-warmth families from these analyses, maternal warmth at baseline significantly moderated the intervention effect on cortisol, Estimate Intervention × Warmth (*SE*) = 1.83 (.61), $p < .01$. The pattern of findings shows that the intervention had a stronger effect on cortisol among the families with lower warmth scores at baseline.

Previously, we reported long-term intervention effects on parent responsiveness for the entire sample (Brotman et al., 2008). For this study, we reexamined the intervention effect on parental warmth within the smaller sample (without the highest warmth families and with a slightly different measure so that it was consistent with the baseline measure of warmth considered in this study) and then conducted a post hoc analysis of the relation between intervention effects on parental warmth and child cortisol. As expected, the intervention significantly increased warmth ($\beta = .15$, *SE* = .06, $p = .01$), and there was a positive, although nonsignificant, association between change in warmth and change in cortisol ($r = .24$, $p = .21$), such that increases in warmth were associated with increases in cortisol response.

Cortisol Change and Later Aggression (Path b)

There was a significant relation of change in cortisol from pre- to postintervention with child aggression at Time 4, Estimate (*SE*) = −1.96 (.62), $p = .007$ (see Figure 2). The relation between cortisol change and later aggression was not moderated by warmth, Estimate intervention × warmth (*SE*) = 1.88 (1.35), $p = .17$.

Taken together, these results meet the joint significance test for mediation of child aggression because both paths *a* (intervention effects on cortisol) and *b* (change in cortisol and later behavior) were significant (MacKinnon et al., 2002).

Intervention Effect on Child Aggression (Path c)

Brotman and colleagues previously reported that there was a significant intervention effect on Time 4 aggression across the entire sample (Brotman et al., 2008). After the removal of the high warmth families,

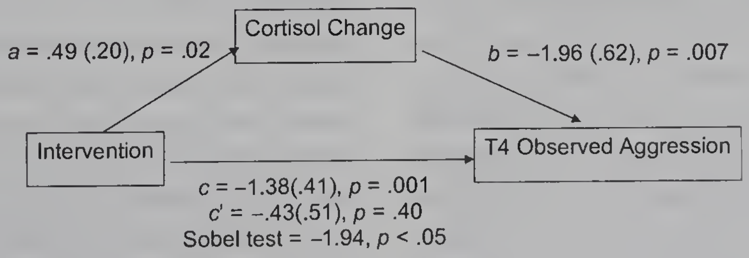

Figure 2. Estimates for indirect intervention effect for lower warmth group (warmth < 1).
Note. N = 57; subsample of high warmth (warmth score = 1) has been removed. a = intervention effect on cortisol change; *b* = cortisol change on aggression; *c* = total intervention effect on aggression; *c′* = total intervention effect on aggression, adjusting for the mediator (cortisol change).

there was a significant intervention effect on Time 4 aggression, $c = -1.38$ (.41), $p = .001$ (see Figure 2). This effect was not moderated by warmth, Estimate Intervention × Warmth (*SE*) = 8.03 (5.91), $p = .20$.

Intervention and Child Aggression Adjusted for Mediator (Path c′)

The results from the previous three sections show that the mediation link between the intervention, cortisol, and later aggression was supported (paths *a* and *b* were significant; see Figure 1). In this section, we test paths *c* and *c′* (whether the effect of intervention on aggression is no longer significant after adjusting for the mediator). As described above, the intervention effect on aggression (path *c*) was significant, $c = -1.38$ (.41), $p = .001$. As expected in complete mediation, regression analyses showed that after adjusting for the mediator (change in cortisol), the intervention was no longer significantly correlated with later aggression, $c' = -.43$ (.51), $p = .40$.

Post hoc analyses revealed that changes in cortisol accounted for 69% of the intervention effect on child aggression. We find further support for the mediating role of cortisol on aggression using the Sobel test (Sobel test = −1.94, $p < .05$; see Figure 2).

To summarize, after removing the highest warmth families because their children did not display aggression at baseline or Time 4, there was an intervention effect on cortisol (that was strongest for the lower warmth families) and intervention-induced change in cortisol response mediated the intervention effect on aggression. Over two thirds of the intervention effect on Time 4 aggression during a parent–child interaction was accounted for by the intervention effect on cortisol response in anticipation of a social challenge.

Child Engaging Behavior

Across the entire sample, we documented a significant intervention effect on later child engaging behavior with the parent, 16 months after the intervention, Estimate (*SE*) = .26 (.08), $p = .003$. To be able to compare results from the mediation analyses with those for child aggression, we limited the analyses of engaging behavior to the lower warmth sample only. The intervention effect on engaging behavior was not significant among lower warmth families, Estimate (*SE*) = .12 (.15), $p = .41$, and a change in cortisol from pre- to postintervention was not related to child engaging behavior at T4, Estimate (*SE*) = .09 (.42), $p = .33$; since path *b* was not significant, mediation did not occur for engaging behavior via cortisol change.

Discussion

The current study takes advantage of an experimental trial with young children at high risk for antisocial behavior to further understand the complex nature of relations among the family environment, neurobiological regulation of stress, and developmental psychopathology. In earlier work with this high-risk sample, we found that family intervention that successfully prevented aggression during early childhood (Brotman et al., 2008) also resulted in normalized stress response (Brotman et al., 2007). The current study extends these findings by examining associations between immediate intervention effects on cortisol response and intervention effects on later aggression, with consideration of the family environment. Study findings underscore the importance of parental warmth for the development of cortisol response during early childhood, suggest that the cortisol response system is plastic (amenable to change as a result of psychosocial intervention) in children from high-risk families and those further characterized by lower maternal warmth, and indicate that cortisol response in anticipation of a social stressor predicts later child aggression. Among the subset of families considered in this study of meditational processes, the long-term prevention effect on child aggression was largely explained by immediate intervention effects on cortisol levels. These findings hold important theoretical and practical implications for the development of the stress response, developmental psychopathology, and its prevention.

Although low cortisol has been associated with disruptive psychopathology, studies demonstrating this link remain largely correlational in nature and, for the most part, have been conducted with children already exhibiting problems (Alink et al., 2008). Furthermore, studies linking child cortisol and behavior have not typically characterized the family environment in which these associations are found. The current study investigates the connection between child cortisol and aggression, while also considering family environment. It links intervention-related increases in cortisol in anticipation of a social challenge to the prevention of physical aggression among children at high risk for maladjustment. Findings are consistent with the theoretical proposition that prevention of aggressive behavior, among children at high risk for atypical stress responding, is dependent on changing the stress response system (van Goozen et al., 2007).

The results of this study beg future in-depth probing of the underlying mechanisms linking changes in cortisol to reduced aggression. Of particular interest in this study is how children's anticipation of a social challenge with peers relates to later aggressive behavior during a parent–child play interaction. A theoretical model worth testing is whether or not child physiological stress response impacts cognitive and emotional processes leading to aggression (van Goozen et al., 2007). In theory, restoring a child's physiological stress response to a typical, reactive state may lead to improved emotional and cognitive appraisal of a socially stressful situation, and these skills generalize across settings and over time, resulting in less aggressive reactions (van Goozen et al., 2007). An alternative but related explanation of results may be that children's increased, more typical, reaction to stress may make them more sensitive to stress cues in relationships, which may, in turn, make them less aggressive toward others. Perhaps such increased sensitivity to social stress leads children to be more fearful of the negative consequences of misbehavior, resulting in lower rates of aggression (Raine, 1993). It has also been posited that heightened stress reactivity occurs due to increased "biological sensitivity to context" with negative consequences in an adverse context and positive consequences in a supportive context (Boyce & Ellis, 2005; Ellis & Boyce, 2008). An intervention could act as a supportive context for families. Perhaps, in this sample, a positive behavioral outcome (i.e., low levels of aggressive behavior) as a consequence of increased stress reactivity was especially possible due to the supportive context an intervention offers to a family.

The current study points to the importance of how the early family environment relates to child cortisol response to a stressor. This study's result linking parent and child cortisol response is too preliminary to speculate as to whether or not the association is due to genetic or learned causes; however, it will be important to identify mechanisms leading children to develop cortisol reactivity patterns that are similar to their parents. Future studies may want to examine whether the most direct route to understanding child neurobiology is not via parent psychopathology or parenting, but via parent neurobiology. In addition to the clustering of parent depression, warmth, cortisol, and child engaging behavior and associations between parent and child cortisol, preliminary, post hoc analyses suggested that among lower warmth families, where changes in both responsive parenting and cortisol levels were observed, responsive parenting and child cortisol response changed in a parallel fashion. Together, the sum picture of such correlational results suggests the importance of research testing causal pathways explaining the link between family environment and child neuroendocrine response during the important developmental period of early childhood.

Given that the link between neurobiological change and aggression occurred among lower warmth families in this study, the intervention effect on cortisol and aggression suggests that caregiving is an important element of a compensatory resilience process (see Luthar, Cicchetti, & Becker, 2000) promoting healthy early neurobiological growth among high-risk children. Results suggest that the early family environment of warmth is a significant contextual factor in explaining change in cortisol response and the consequence of such cortisol change on child aggression. Results contribute to the small literature demonstrating biological outcomes from early intervention with young children (Brotman et al., 2007; Dozier et al., 2008; Fisher et al., 2007; Raine et al., 2001). Our findings underscore the importance of considering characteristics of the family environment (e.g., parental warmth) within studies that examine biological and behavioral outcomes from family intervention (Cicchetti & Gunnar, 2008). In intervention children from lower warmth families, cortisol levels in anticipation of a social challenge were found to increase over an 8-month period, from approximately ages 4–5 years. In contrast, in control children from lower warmth families, cortisol levels decreased over this same developmental period. These findings support a developmental model in which moderately low levels of parent warmth place children who are at familial risk for antisocial behavior at even further risk for an atypical stress response. In these lower warmth families, preventive intervention that enhances parenting practices and child social competence (Brotman et al., 2005) may protect against this risk; immediately following intervention, children from lower warmth intervention families exhibited increases in cortisol relative to controls. It is important that future research more definitively establishes the developmental trajectory of normal cortisol response patterns over time among young children and the specific challenge conditions that elicit such a response. Translation of basic research to preventive interventions is dependent on future research, which details the stress buffering mechanisms in the family environment leading to positive neurobiological and behavioral outcomes in high-risk children (Gunnar et al., 2006).

This study also extends previous research (e.g., Fisher et al., 2006) by characterizing the family environment and the subgroups that benefit from intervention. Additional post hoc results suggested that among lower warmth families, the intervention altered both parent warmth and child cortisol, and these changes may be related. Further research is needed to more fully understand how change in parenting may lead to change in child neuroendocrine functioning and behavior. The unique importance of warmth for the development of the neurobiological system is strongly supported by animal studies (e.g., Caldji et al., 2000; Liu et al., 1997), especially an elegant experimental literature of rodent maternal care on rat pup stress response. Unlike the physical process underlying rodent parent warmth (i.e., licking and grooming of their offspring), the measure of human parental warmth as assessed in this study largely consisted of verbal behaviors. It is not known whether findings are specific to verbal behaviors or whether inclusion of physical behaviors (e.g., hugging, physical proximity) would provide a more complete picture of this process. As these lower warmth families were also characterized by parent depression and hypocortisolism, future exploration of the construct of warmth and its relation to other aspects of parenting behavior and neurobiology in high-risk families appears warranted.

Future studies should also consider additional outcomes of child functioning and parent–child relations. In the current study, increased cortisol in anticipation of a social challenge was related to lower rates of aggressive behavior during parent–child interactions. It is possible that higher cortisol levels may be related to other outcomes, including negative outcomes such as poor physical health. In this study, aggression, not child engaging behaviors, was related to child cortisol change. Perhaps other positive child outcomes, such as child emotion coping or academic success, would be affected by change in child cortisol response. Also, in empirical studies of cortisol and aggression, it has been argued that it is best to examine cortisol under stressful conditions (i.e., cortisol reactivity) rather than relying on diurnal cortisol (van Goozen et al., 2007); the cortisol patterns unique to aggressive behavior may be specific to or more easily detected in stressful or challenging conditions (McBurnett, Lahey, Rathouz, & Loeber, 2000; Pajer, Gardner, Rubin, Perel, & Neal, 2001; Popma et al., 2006; van Goozen et al., 2000). Therefore, future studies may want to determine what kinds of outcomes are uniquely affected by change in cortisol response to challenge versus diurnal patterns of cortisol. Similarly, the specific context of the cortisol stressor could predict different subtypes of aggression. For instance, if the cortisol response paradigm tested reactivity or lack of reactivity to others' distress, rather than reactivity to novel peers as in this study, then the lack of reactivity to others' distress might better predict emotional callousness (Dadds & Rhodes, 2008).

In addition to further understanding relations among family environment, child cortisol response, and behavior, this study provides further evidence in support of early family intervention for high-risk children. Specifically, new findings on child outcomes in this study include intervention effects on observed child engaging behavior, 16 months after intervention.

There are a number of important study limitations that are worthy of consideration. First, we had to eliminate families with the highest scores on warmth from the mediation analyses. As a consequence, none of the findings can be generalized to families characterized by high warmth. Future studies should conduct mediation and moderation analyses of intervention effects on aggression to formally test many of the proposed hypotheses. In addition, the generalizability of study findings is limited due to the unique nature of the sample. In terms of the sample characteristics, attempts to replicate the current findings should consider whether similar effects on cortisol can be documented among children living in environments involving different forms of stress. The current findings should encourage attempts to examine effects on physiology in much larger samples, where unique subgroups can be examined more comprehensively. Despite the need for replication, the current findings demonstrate statistically significant mediating effects. This suggests the potential value of conducting future work examining mechanisms linking context, behavior, and stress response in children. Such future work might include longer term outcomes assessed over multiple time points.

As with the initial report on intervention effects on cortisol response (Brotman et al., 2007), the current study is limited by the lack of a low-risk comparison group. Including such a group, studied with identical methods, is key given the robust effects of context on both behavior and cortisol. However, the association between increased cortisol response and lower rates of aggression suggest that intervention effects on cortisol response were positive and that the intervention worked to normalize the stress response. The study is also limited by its reliance on one measure of parent warmth. It would have been desirable to have a more comprehensive measure of this construct that includes both verbal and physical aspects of warmth. Also, we do not know whether study findings generalize to child behavior outside the home environment. That is, we did not measure behavior with peers, and, therefore, it is not known whether the relation between cortisol and behavior is limited to the context of parent–child interactions.

Much remains to be explained about the role of the early family environment, stress response, and the prevention of psychopathology in high-risk children. It is imperative that prevention studies continue to examine neurobiological as well as behavioral systems and outcomes (Cicchetti & Gunnar, 2008). Additionally, we would urge investigators to consider many aspects of the caregiving environment as potential moderators of these mediational processes (Fairchild & MacKinnon, 2009). Such steps would advance the field considerably in understanding the complex interplay of the early family environment, neurobiological functioning and the development, and prevention of aggression and psychopathology.

Early-Childhood Poverty and Adult Attainment, Behavior, and Health

Greg J. Duncan

Kathleen M. Ziol-Guest
Institute for Children and Poverty

Ariel Kalil
University of Chicago

This article assesses the consequences of poverty between a child's prenatal year and 5th birthday for several adult achievement, health, and behavior outcomes, measured as late as age 37. Using data from the Panel Study of Income Dynamics (1,589) and controlling for economic conditions in middle childhood and adolescence, as well as demographic conditions at the time of the birth, findings indicate statistically significant and, in some cases, quantitatively large detrimental effects of early poverty on a number of attainment-related outcomes (adult earnings and work hours). Early-childhood poverty was not associated with such behavioral measures as out-of-wedlock childbearing and arrests. Most of the adult earnings effects appear to operate through early poverty's association with adult work hours.

Some 4.2 million infants, toddlers, and preschoolers lived in poverty in the United States in 2007. For a single mother with two children, this meant that total income was less than $16,705; many poor families had income well below that amount (U.S. Census Bureau, 2008). Poverty and its attendant stressors have the potential to shape the neurobiology of the developing child in powerful ways, which may lead directly to poorer outcomes later in life. Poverty in early childhood can also affect adult attainment, behavior, and health indirectly through parents' material and emotional investments in children's learning and development.

The sensitivity of early childhood to environmental influences has been demonstrated in a wide range of infant, toddler, and preschooler intervention studies. Many descriptive studies show that, relative to nonpoor children, poor children will be less successful in school and, as adults, in the labor market, have poorer health, and be more likely to commit crimes and engage in other forms of problem behavior (see Holzer, Schanzenbach, Duncan, & Ludwig, 2007, for a review of these studies). Despite these associations, it is far from clear to what extent poverty *itself* is the cause of these differences. Our primary goal in this study is to obtain relatively unbiased estimates of the total effects association between early-childhood poverty and adult attainment, behavior, and health. Extending the work of Duncan, Brooks-Gunn, Yeung, and Smith (1998), we use the most recent data from the Panel Study of Income Dynamics (PSID) to examine the long-run (i.e., as late as age 37) impacts of low income early in life, net income later in childhood, and other correlated family factors surrounding a child's birth.

Background

Emerging evidence from human and animal studies highlights the critical importance of early childhood for brain development and for setting in place the structures that will shape future cognitive, social, emotional, and health outcomes (Sapolsky, 2004; Shonkoff & Phillips, 2000). How poverty early in childhood might affect these structures has been

a matter of considerable research. Economic models of skill acquisition illustrate the potential importance of early environmental conditions on adult cognitive and noncognitive skills (Knudsen, Heckman, Cameron, & Shonkoff, 2006). Among other things, low income during early childhood may limit parents' ability to purchase adequate-quality health care or education during children's formative years.

Complementary studies in psychology and social epidemiology illustrate that both in utero environments and early-childhood experiences have long-run impacts on adult physical and mental health (Barker, Eriksson, Forsen, & Osmond, 2002; Danese, Pariante, Caspi, Taylor, & Poulton, 2007; Poulton & Caspi, 2005). Epidemiologists have suggested that early-childhood stressors related to low income could alter or dysregulate biological systems, with adverse implications for future health (Godfrey & Barker, 2000). Psychologists posit that poverty and economic insecurity undermine parents' mental health and parenting behavior. In animal models, optimal "mothering" behavior in critical periods of early development is associated with lifelong stress reactivity and cognitive strength (Sap, 2004).

Duncan and Brooks-Gunn (1997) were the first to take a broad look at the possible longer run consequences of early-childhood poverty. Twelve groups of researchers working with 10 different nonexperimental but longitudinal data sets estimate longitudinal models of early-childhood income effects on later attainment, behavior, and health. On the whole, the results suggest that family income has substantial, albeit selective associations with children's subsequent attainments.

First, family income had consistently larger associations with measures of children's cognitive ability and achievement than with measures of behavior, mental health, and physical health. Second, family economic conditions in early childhood appeared to be more important for shaping ability and achievement than did family economic conditions during adolescence. And third, the association between income and achievement appeared to be nonlinear, with the biggest impacts at the lowest levels of income.

Why the Timing of Income May Matter

The present study builds on the key conclusion from Duncan and Brooks-Gunn (1997) that family economic conditions in early childhood appear to matter more for shaping later development than economic conditions during adolescence. Developmental theory suggests that given the nature of developmental tasks, sensitivity to change, and interactions with the environment, early childhood is a developmental period that may be especially sensitive to environmental conditions affected by family income (Shonkoff & Phillips, 2000). Moreover, early courses of development may reach well into adulthood. Waddington (1957) has described development as proceeding along the branches of a tree—although changes in developmental trajectories can occur at any point at which a new branch is formed, the ability of the individual to alter his or her developmental course substantially becomes increasingly difficult over time. These themes are reflected in economic, psychological, and neurobiological perspectives on the importance of early childhood.

Cunha, Heckman, Lochner, and Masterov (2005) proposed an economic model of development in which preschool cognitive and socioemotional capacities are key ingredients for human capital acquisition during the school years. In their model, "skill begets skill" as early capacities can affect the productivity of school-age human capital investments. Economic deprivation in early childhood could create disparities in school readiness and early academic success that persist or widen over the course of childhood. The theory proposed by Heckman and colleagues is novel in economics for its developmental perspective: Typically, the economics literature has ignored the notion that the effects on children's development of economic conditions may depend upon childhood stage and instead focuses on the role of "permanent" income, with the assumption that families anticipate bumps in their life-cycle paths and can save and borrow freely to smooth their consumption across these bumps (Blau, 1999).

Developmental psychology clearly stresses the importance of understanding children's distinct developmental stages (Bronfenbrenner & Morris, 1998). In the context of poverty studies, the greater malleability of children's development and the overwhelming importance of the family (as opposed to school or peer contexts) for preschoolers lead us to expect that family income in early childhood may be much more important for shaping children's ability and achievement than conditions later in childhood (Bronfenbrenner & Morris, 1998; Shonkoff & Phillips, 2000). For example, to the extent that poverty increases mothers' psychological stress or harsh parenting behaviors (Yeung, Linver, & Brooks-Gunn, 2002), this will be especially important during early childhood given the primacy of sensitive mother–child interactions for the development of young children's emotion regulation (Waters & Sroufe, 1983). Mastery of emotion regulation in early childhood can have long-run impacts on children's achievement, behavior, and health (Fox, 1994). Similarly, to the extent that cognitively enriching early home environments lay the groundwork for success in preschool and beyond, parents' ability to purchase books, toys, and enriching activities during this stage of development is paramount.

As its name suggests, the "fetal origins" hypothesis also points to a sensitive period in early childhood. In this case, the in utero environment is critical. This hypothesis posits an in utero programming process whereby stimulants and insults during this critical period of development have long-lasting implications for physiology and disease risk (Barker et al., 2002; Godfrey & Barker, 2000; Hertzman, 1999). Low income during the prenatal period may be associated with fetal undernutrition, low birth weight, or slow growth in the first 2 years of life. A pattern of small size at birth and low body mass index (BMI) at age 2, followed by rapid weight gain after age 2, is a risk factor for the development of insulin resistance and a disproportionately high fat mass in relation to muscle mass (Barker, Osmond, Forsén, Kajantie, & Eriksson, 2005; Barker et al., 2002). Low income is also associated with food insecurity, which has been associated with overweight and obesity in childhood, adolescence, and adulthood, especially among females (Frongillo, 2003). Overweight and obesity, in turn, can be physically debilitating, which could lead to a negative cycle of depression, overeating, or stress (Stunkard, Faith, & Allison, 2003).

Methods for Assessing Causal Impacts of Poverty

Researchers generally do not dispute simple correlations between income and child developmental outcomes. However, there is much controversy about whether these income effects are causal. The key estimation problems in assessing the causal impact of family income on child well-being are twofold: timing of measurement and omitted-variable bias. Theory suggests that the development of children's cognitive and social skills is a time-consuming process. Attainments in, say, adolescence, may well be a product of economic conditions not only in adolescence but also in early and middle childhood and possibly during the prenatal period as well (Barker, 1998). Estimates of models of income effects that measure income concurrently with the child outcomes risk bias if income is volatile across childhood. As there is abundant evidence that income is indeed volatile (Duncan, 1988), a longitudinal perspective on the role of income in shaping child well-being appears crucial.

Even supposing that income is measured well across the entire period of childhood, it is difficult to isolate the causal impact of income, as many factors might jointly determine family income and child development and parental cognitive ability is a prime example (Rowe & Rodgers, 1997). Parents with higher cognitive ability are usually more successful in the labor market. At the same time, they are more likely to provide a higher quality learning environment for their children, regardless of how much money they may be spending on books or computers. Some studies find large reductions in the estimated impacts of income once adjustments for omitted-variable bias are implemented (Blau, 1999; Mayer, 1997).

State or national policies sometimes change in ways that provide researchers with opportunities to relate exogenous, policy-induced changes in family income to child well-being. Such is the case with the study by Dahl and Lochner (2005), who took advantage of the fact that the United States increased the generosity of its Earned Income Tax Credit (EITC) program during the 1990s. The EITC provides a refundable tax credit to low-income working families. The maximum size of the annual credit is now quite substantial—$4,824—and it increased by about $2,300 in the middle 1990s. Dahl and Lochner estimated that a $3,000 increase in family income in early and middle childhood boosts reading achievement by about one tenth of a standard deviation and math achievement by about half that amount. These effects were two to three times as large, however, for children of non-White, unmarried, and less educated mothers, which corresponds to another key conclusion in Duncan and Brooks-Gunn (1997)—namely, that income effects are nonlinear such that increases in income matter more for lower income children than their higher income counterparts.

The different disciplines' approaches to these questions each have their own merits and limitations. Developmental research articles on the impacts of poverty, although often paying close attention to the processes or pathways linking poverty with developmental outcomes, typically employ only a handful of family-based demographic covariates, opening the door for a host of omitted-variable biases. Research in economics, which generally takes a "total effects" (reduced-form) approach, typically opts to exploit some kind of natural experiment—siblings differences within families or temporal or areal variation in income induced by policy (e.g., EITC expansion) or macroeconomic (e.g., unemployment differences) fluctuations. These approaches have stronger claims to internal validity (reduced bias) but, concentrating as they often do on narrow subpopulations, often sacrifice external validity. Such studies also often yield very imprecise estimates. And no prior study has been able to link income-based economic conditions in early childhood to outcomes measured well into adulthood.

We use data from a long-running national survey to surmount some of these limitations. As in many studies in economics, we aim to estimate the total effects (as opposed to a mediational model) of early-childhood poverty and adult attainment, behavior, and health. By taking a population-based approach, we minimize threats to external validity. And, in contrast to many developmental studies, we employ an unusually rich and powerful array of covariates to control for omitted-variable biases. In particular, our estimates of the impact of early-childhood poverty on adult attainment, behavior, and health include controls for income in middle childhood and adolescence. It is very difficult to think up omitted-variable bias stories involving early income that would not be controlled in large measure with the inclusion of income later in childhood.

This study draws on national data from the PSID, the longest-running longitudinal study of household income in the United States, to estimate linkages between income early in childhood and adult outcomes. Ours is the first study to link high-quality income data across the entire childhood period with adult outcomes measured as late as age 37. Our strategy is to measure income in every year of a child's life from the prenatal period through age 15, distinguishing income early in life (prenatal through 5th year) from income in middle childhood and adolescence. Our analyses relate an array of adult achievement, social assistance, health and behavior measures to these childhood stage-specific measures of income, plus a host of relevant demographic control variables measured around point of the child's birth. The wide range of adult outcomes we consider include educational attainment, earnings, work hours, receipt of food stamps and cash assistance, nonmarital childbearing, crime, and mental and physical health.

Method

Sample

We use 1968–2005 data from the PSID, which has followed a nationally representative sample of families and their children since 1968 (http://psidonline.isr.umich.edu). Our general strategy is to select children observed in the PSID between their prenatal year and at least age 25, although a number of our outcomes are drawn from the 2005 interview, in which individuals ranged from ages 30 to 37.

Our target study sample consists of the 2,599 individuals born to a sample member into PSID households between 1968 and 1975, who were thus between ages 30 and 37 in 2005. Sample losses to nonresponse are substantial, prompting us to use the PSID's attrition-adjusted weights in all of our analyses. We required that these individuals have complete data on control variables measured around the time of their birth (defined next), leaving 93% of the birth sample ($n = 2{,}414$). We further required that these individuals be in response families in at least 12 of the 17 years from prenatal year to age 15, a restriction that eliminated 479, or 18% of the original sample. Of the remaining 2,120, 1,589 participated in the PSID in adulthood and had nonmissing data on at least one outcome and a PSID attrition-adjusted weight. Sample sizes vary by outcome owing to when it was measured, and in some cases (distress and body mass) only information was collected from individuals who were "heads" or "wives" in PSID households.

Childhood Income

We used the PSID's high-quality edited measure of annual total family income, inflated to 2005 levels using the Consumer Price Index (CPI). We averaged these annual income measures across three periods: the prenatal year through the calendar year in which the child turned 5, ages 6–10, and ages 11–15. With income reported for calendar years and conceptions occurring continuously, there was some imprecision in matching income to the prenatal year and beyond. If a child was born prior to July 1, we took the prenatal year to be the prior calendar year. If the birth was after July 1, then the prenatal year was considered to be the year in which the birth occurred. Similarly, we defined "under age 6" as the last calendar year before the child's sixth birthday. Thus defined, our "early-childhood" period consists of seven calendar years.

To account for a possible differential impact of increments to low as opposed to higher family income, we allowed the coefficients on average income within each childhood period to have distinct linear effects for average incomes up to $25,000 and for incomes $25,000 and higher. Considerable experimentation confirmed the utility of the $25,000 "knot" in the case of the adult outcomes most sensitive to variations in early income; lower income knots reduced sample sizes for, and therefore the precision of, the low-income effect estimates; higher thresholds typically produced noteworthy reductions in the low-income segment coefficients.

Adult Outcomes

Dependent variables in our analyses spanned achievement, health, and behavioral domains. Years of completed schooling are based on the most recent report of schooling available in the data. In all cases, the report was taken when the individual was at least 22 years old and in most cases the individual was at least 25.

Adult work hours and natural logarithm of the child's adult earnings were gleaned from all available annual reports of earned income and work hours reported by or for the child when the child was aged 25 or older. As with childhood income, we inflated the dollar values of earnings to 2005 price levels using the CPI. To adjust earnings for age and calendar year, we regressed all of our yearly earnings observations on sets of dummy variables measuring the age of the respondent in the given year, and the calendar year of measurement. We then generated residuals from this regression for each sample individual's earnings observations and averaged these residuals across all of the yearly earnings observations that a given individual generated. We centered these average residuals around the sample mean by adding them to the overall sample mean earnings. We repeated this process to adjust work hours for age and year effects. As a final step in the case of earnings, we took the natural logarithm.

Food stamp and Aid to Families with Dependent Children/Temporary Assistance to Needy Families (AFDC/TANF) receipt are measured at the household level and are taken from all available surveys when the child was aged 25 or older. Although some adults under age 25 are program recipients, it was difficult to assign transfer income sources to individual household members prior to around age 25. We created calendar-year values of both programs and inflated the values to 2005 price levels using the CPI. Like average annual earnings, we adjust for age and calendar-year effects by regressing all food stamp and AFDC/TANF values on age and calendar-year dummies, obtained the residuals, and calculated the average residuals and mean values across all available years for a given individual. We estimate food stamp models for the entire sample but AFDC/TANF models only for the females.

Our measure of poor overall health was based on the most recent response to the question "I have a few questions about your health, including any serious limitations you might have. Would you say your health in general is excellent, very good, good, fair, or poor?" Individuals are considered in poor health if they responded that their health was either fair or poor. Although the results are not reported in the tables, we also ran our models using a continuous measures of health-assigning integer values of 1–5 for these respective categories and with an alternative scaling of *excellent* = 100, *very good* = 85, *good* = 70, *fair* = 30, and *poor* = 0. Our regression results are robust to this specification. Because we used the most recently available report of self-rated health, our regression analyses of this outcome also include calendar-year dummy variables for when the individual's report was taken.

Our measure of adult BMI was calculated based on reports in the 2005 survey of heads and wives of their weight in pounds and their height in feet and inches. We calculate BMI using the following formula:

$$\frac{\text{Weight} \times 703}{\text{Height}^2},$$

where weight is measured in pounds and height is measured in inches. We follow convention and define "overweight" as a BMI ≥ 25 (Centers for Disease Control and Prevention, 2003).

Our measure of psychological distress was based on responses to a 2003 administration to heads and wives of the K-6 NonSpecific Psychological Distress Scale, developed by Ronald Kessler. It includes six items, ranging from *all of the time* = 4, *most of the time* = 3, *some of the time* = 2, *a little of the time* = 1, and *none of the time* = 0. The questions are: "Now, I am going to ask you some questions about feelings you may have had over the past 30 days." In the past 30 days, about how often did you feel: (a) so sad nothing could cheer you up? (b) nervous? (c) restless or fidgety? (d) hopeless? (e) that everything was an effort? and (f) worthless? The scores are summed; a score of 13 or higher is considered to be the threshold for the clinically significant range of the distribution of nonspecific psychological distress, which we refer to here as ''high distress.'' As with the general health measure, we also analyzed a continuous measure of distress and found the same general patterns.

The crime outcomes consisted of responses to questions asked in the 1995 interviewing wave regarding past arrests and time in jail. A dichotomous ''arrest'' outcome was coded for an affirmative response to the question: ''Not counting minor traffic offenses (has he/has she/have you) ever been booked or charged for breaking a law?'' A dichotomous ''jail'' outcome was coded for an affirmative response to the question: ''(Has he/Has she/Have you) ever spent time in a corrections institution like a jail, a prison or a youth training or reform school?'' Owing to the infrequency of arrest and incarceration among females, this analysis was restricted to males.

Finally, our nonmarital birth outcome is based on a dichotomous indicator of whether the individual (females only) reported a nonmarital birth prior to her 21st birthday in the PSID's fertility and marital histories.

Control Variables and Regression Procedures

To avoid attributing to income what should be attributed to correlated determinants of both childhood income and our outcomes of interest, we included the following control variables in all of our regressions: (a) dummy variables for seven of the eight birth years, (b) race (Black, other, with White the reference category), (c) child's sex (male = 1), (d) whether the child's parents were married and living together at the time of the birth, (e) the age of the mother at the time of the birth, (f) whether the child lived in the South at the time of the birth, (g) the total number of siblings born to the child's mother, (h) whether the child was the firstborn to his or her mother, (i) years of completed schooling of the household head (usually the father in two-parent households, the mother in single-parent households) of the child's household in the birth year, and (j) the head's score on a sentence completion test administered in the 1972 interviewing wave.

Additionally, we include several variables taken in the earliest years of the PSID and use the survey response from the year closest to the child's birth. All but the first of these measures are collected from the household head. First, we include the response to an interviewer observation regarding the cleanliness of the respondent's dwelling. Responses ranged from 1 (*very clean*) to 5 (*dirty*); therefore, higher values represent perceptions of less clean home environments. Dunifon, Duncan, and Brooks-Gunn (2001) found significant links between this measure and children's completed schooling. Second, we include an index of parental expectations for children that reflects expectations for their own as well as their children's futures. Components of this scale include responses to statements such as having explicit plans for children's education and jobs. Third, we include two motivational measures: (a) an assessment of the importance of challenge versus affiliation and (b) a measure of an individual's sense of personal control. Both of these measures are associated with long-run labor market success (Duncan & Dunifon, 1998). The challenge versus affiliation measure was created by averaging responses to two questions ''Would you liked to have more friends, or would you like to do better at what you try?'' and ''Would you prefer a job where you had to think for yourself, or one where you work with a nice group of people?'' A score of 1 indicates preference for challenge, whereas those who preferred to have more friends or work with nice people received scores of 0. Sense of personal control was obtained through three questions: ''Have you usually felt pretty sure that your life will work out the way you want it to, or have there been more times when you haven't been sure about it?'' ''When you make plans ahead, do you usually get to carry out things the way you expected, or do things usually come up to make you change your plans?'' and ''Would you say that you nearly always finish things once you start them, or do you sometimes have to give up before they are finished?'' Responses were scored 1 for a positive response, 0.5 for an equivocal response, and 0 for a negative response. Finally, we included a measure of risk avoidance, which ranges from 0 to 9 capturing avoiding risk on everyday things including having at least one car in good condition, all cars are insured, using seatbelts, health insurance or free medical care, family does not smoke, and family has some savings.

All of our regressions were run in STATA SE 9.0 standard error, use the PSID's weights to adjust for differential sampling fractions and attrition, and adjust for origin–family clustering on the mother using Huber–White methods. Experimentation with both weighted and unweighted regression estimates revealed marked differences in coefficients on early-childhood income in several cases, which led to using the weights in the regression analyses—a point discussed further in the Results section.

Continuous outcomes (ln earnings, work hours, and completed schooling) were analyzed with ordinary least squares (OLS), measures with substantial concentrations of zeroes (food stamp and AFDC/TANF receipt) were analyzed with Tobit regressions, and dichotomous outcomes (poor health, high distress, ever arrested, ever jailed, and nonmarital birth before age 21) were analyzed with logistic regression. The arrest and incarceration models are only run on males, whereas the AFDC/TANF and nonmarital childbearing models are only run on females. To facilitate their interpretation, logistic regression coefficients and standard errors are expressed in the tables in the form of marginal effects (and their associated standard errors), computed using the MFX command in STATA. These show the change in the probability (as opposed to the odds) of the outcome occurring associated with a unit change in the given independent variable.

Results

Sample Description

Case counts, means, and standard deviations of each of our outcome variables are provided in Appendix A. These summary statistics are weighted using the weight for the year in which the outcome was measured (high distress, BMI, overweight, arrest, and incarceration), or the most recent weight of the PSID (completed schooling, earnings, work hours, food stamp, and AFCD/TANF receipt and nonmarital childbearing). Descriptive statistics are presented for both the overall sample and for children whose prenatal-to-age-5 incomes averaged: (a) below the official poverty line, (b) between 1 and 2 times the poverty line, and (c) more than twice the poverty line. The final column of Appendices A and B provide information on the statistical significance (at $p < .05$ or below, two-tailed test) of the mean differences across the three groups.

Appendix A shows striking differences in adult outcomes depending on whether childhood income prior to age 6 was below, close to, or well above the poverty line. Compared with children whose families had incomes of at least twice the poverty line during their early childhood, poor children complete 2 fewer years of schooling, work 451 fewer hours per year, earn less than half as much, received $826 per year more in food stamps as adults, and are more than twice as likely to report poor overall health or high levels of psychological distress. Further, poor children have BMIs that are 4 points higher than those well above the poverty line, and are almost 50% more likely to be overweight as adults. Poor males are twice as likely to be arrested and for females, poverty is associated with a $200 annual increase in cash assistance, and a sixfold increase in the likelihood of bearing a child out of wedlock prior to age 21.

Appendix B reports the weighted descriptive statistics of the childhood period income measures and control variables for the total sample, as well as by poverty status in early childhood. Not surprisingly, children with average annual incomes below poverty in the earliest period have lower average income in all three periods compared with the other two groups. Additionally, the poorest children are less likely to be White and born into an intact family, and more likely to be born in the South, have younger mothers, more siblings, household heads with lower test scores and educational attainment, homes rated as dirtier by interviewers, lower parental expectations, and household heads who report less preference for challenge versus affiliation, less personal control, and less risk avoidance compared with their higher income counterparts.

Multivariate Results

To motivate the estimates from our full regression models, we present in Table 1 standardized coefficient results from a series of descriptive regressions. Across the columns of the first row (Model 1), each outcome is regressed only on a measure of 17-year average childhood income. For ease of calculation of standardized coefficients for our health outcomes, we estimate OLS regressions using continuous measures of general health and distress. Further, to calculate the standardized logistic regression coefficients, we use the following equation from Menard (2004): $b^* = (b)(s_x)(R)/s_{logit(\hat{y})}$, where b is the logit coefficient, s_x is the standard deviation of x, R is the square root of the R^2 from the logit regression, and $s_{logit(\hat{y})}$ is the standard deviation of the predicted value of y.

As we express estimates as standardized regression coefficients, entries in the first row amount to simple correlations between income and each of the outcomes. The directions of all of the correlations are as expected—positive for ''good'' outcomes and negative for ''bad'' ones—and significant for all

Table 1
Standardized Regression Coefficients From Various Weighted Models of Childhood Income and Adult Outcomes

	Income measure	Schooling (years)	Annual earnings	Annual work hours	Food stamps	AFDC/ TANF	Health status	Distress	BMI	Arrested	Nonmarital birth
Model 1: No controls; 17-year average childhood income	Prenatal to age 15	.34**	.31**	.15**	−.25**	−.13**	−.13**	−.11**	−.15**	−.17*	−.38**
Model 2: Background controls; 17-year average childhood income	Prenatal to age 15	.14**	.23**	.11**	−.08*	−.08†	−.02	−.06	−.02	−.09	−.26**
Model 3: Background controls; natural logarithm of 17-year average childhood income	Prenatal to age 15	.22**	.37**	.20**	−.24**	−.07	−.08*	−.09	−.09†	−.13†	−.18**
Model 4: Background controls; natural logarithm ofaverage stage-specific childhood income	Prenatal to age 5	.10*	.27**	.20**	−.08†	−.08	.07	.00	−.04	−.11	.02
	Ages 6–10	−.04	.06	−.03	−.12*	.07	−.05	.14†	−.09	.11	.07
	Ages 11–15	.18**	.08	.06	−.06	−.07	−.11†	−.25**	.04	−.17†	−.27**

Note. Ordinary least squares analysis for schooling, earnings, work hours, food stamps, Aid to Families with Dependent Children/Temporary Assistance to Needy Families (AFDC/TANF), health status, distress, and body mass index (BMI); logit analysis for arrests and nonmarital births. Standardized regression coefficients for the logistic regression employ procedures from Menard (2004).
†$p < .10$. *$p < .05$. **$p < .01$.

outcomes. The largest correlations, all in the .3–.4 range, are found for schooling, adult earnings, and nonmarital births.

In the second row (Model 2) results, our extensive set of background control variables, all measured either before or right around the time of birth, is added to each of the regressions. All of the coefficients become smaller (in absolute value); in the case of the three health measures and arrests, the coefficient on childhood income drops below the .05 threshold of statistical significance. Thus, a substantial portion of the simple correlation between childhood income and most adult outcomes can be accounted for by the disadvantageous conditions associated with birth into a low-income household.

To assess whether increments to low income may matter more than increments to the incomes of children growing up in middle-class or affluent families, we regressed the adult outcomes on the natural logarithm of the 17-year average childhood income plus background controls. Whereas our first two models assumed that, say, a $5,000 increment to a poor family's income had the same beneficial effect on a child's adult outcomes as a $5,000 increment to an affluent family's income, the logarithmic transformation assumes equal percentage effects. So, for example, the logarithmic model presumes that a 50% (and $10,000) increase in average childhood income from $20,000 to $30,000 has the same effect as the 50% (but $50,000) increase from $100,000 to $150,000. Higher standardized coefficients (in absolute value) in logarithmic as opposed to linear models would suggest that dollars matter more for the developmental outcomes of children reared in lower than higher income households.

As shown in the third (Model 3) row of Table 1, the standardized coefficients for the logarithmic models are uniformly higher than coefficients for the linear models (Model 2) in the case of achievement outcomes: completed schooling, earnings, work hours, and food stamps. Health outcomes and AFDC/TANF receipt are little affected by the change, whereas coefficients increase only slightly for arrests and actually fall for nonmarital births. The pattern of results for these adult outcomes is broadly consistent with the conclusions that Duncan and Brooks-Gunn (1997) reached for childhood outcomes: Income appears to be more predictive of achievement-related than either behavior or health outcomes.

To address the issue of the childhood stage-specificity of income effects, the final (Model 4) regressions in Table 1 replace the single 17-year average log childhood income measure with three stage-specific measures of log income. All background controls are included in these models. With each childhood stage accounting for approximately one third of childhood, we would expect that the three coefficients should (approximately) sum to the all-childhood coefficient presented in Model 3. If childhood income mattered equally across all three stages, the three coefficients should be roughly the same size and about one third the magnitude of the Model 3 coefficients.

In the case of adult earnings and work hours, early-childhood income appears to matter much more than later income. For work hours, the standardized coefficient on prenatal-to-age 5 log average income (.20) is just as large as the Model 3 coefficient on all-childhood log average income, suggesting little role for income beyond age 5. Early income also has a statistically significant coefficient ($p < .05$) in the case of completed schooling, but in this case adolescent income has a considerably larger standardized coefficient. Adult health outcomes and nonmarital births have strong associations with childhood income, but only with childhood income during adolescence.

Taken together, the descriptive regression results shown in Table 1 suggest that both childhood stage and outcome domain matter for understanding links between childhood income and adult success. Moreover, many of the adult outcomes appear to be more sensitive to increments to low as opposed to middle-class or high family incomes.

These lessons are incorporated into our main regression models, shown in Table 2 for achievement outcomes and program participation, Table 3 for health outcomes, and Table 4 for behavioral outcomes. Coefficients and standard errors for the childhood-stage-specific income variables are presented first. For each stage's income, two coefficients are presented, the first reflecting the estimated effect of an additional $10,000 of annual income in the given stage for children whose income in that stage averaged < $25,000 and the second reflecting comparable effects for higher income children (all three sets of income variables, plus other controls, are included in all regressions). The column labeled "different slopes" reports results from a statistical test of the null hypothesis of equal within-period slopes. The final row shows results for a test of equality of all three < $25,000 segment slopes. In contrast to Table 1, coefficients in Tables 2–4 are unstandardized and therefore show changes in originally scaled dependent variables associated with $10,000 increments to average childhood stage-specific income.

Table 2 shows that additional income in the prenatal to age 5 period for the lowest-income children is associated with significantly greater adult earnings and work hours, and less food stamp receipt. To ensure that our spline models fit the earnings and work hours data reasonably well, we estimated models with early income represented with a set of dummy variables, and controls for later period incomes (ages 6 through 10 and ages 11 through 15). As shown in Figures 1 and 2, which include 95% confidence bands, the income range in which income responses flattened out was roughly between $20,000 and $30,000, thus supporting our use of a knot at $25,000.

We can illustrate the nature of the income effects of early-childhood income using the natural log earnings regression. The "0.52" coefficient means that, adjusting for income later in childhood and the other control variables listed in Table 2, an additional $10,000 per year of family income between the prenatal year and the child's fifth birthday is associated with an increase in the natural logarithm of adult earnings of 0.52—or 68.2% ($e^{52} = 1.682$). In contrast, increments to early-childhood income for higher-income children (i.e., annual average family incomes above $25,000) are associated with an insignificant 0.05 increment in log earnings. The p value ($p < .05$) reported in the "different slopes" column indicates that the slope for those with incomes less than $25,000 per year in early childhood is significantly different from the slope for those with incomes greater than $25,000 in the same period. Increments to incomes in middle childhood and adolescence are estimated to have nonsignificant impacts on log earnings, even among low-income children. The final row of Table 2 indicates that the three coefficients on the < $25,000 spline slopes across the childhood stages are significantly different from one another at the $p = .08$ level.

Results for work hours are broadly similar to those for earnings—a highly significant estimated impact of early childhood but not later childhood income. In this case, a $10,000 annual increase in the prenatal to age 5 income of low-income families is associated with more than 500 additional work hours per year after age 25. Tobit spline regressions for food stamps for the entire sample suggest that increases in income in all childhood periods for the lowest income children are associated with statistically significant reductions in food stamps. Both the coefficients on food stamps and welfare proved

somewhat sensitive to outliers, resulting in a decision to truncate both dependent variables at the 99th percentiles of their respective distributions—$4,913 in the case of annual food stamp receipt and $2,954 in the case of annual AFDC/TANF receipt. Additionally, when separate food stamp models for males and females were conducted, we found a much larger and statistically different effect of early poverty for females than for males. The respective coefficients and standard errors for females were −$483 (268) and for males were −$260 (125). The female coefficient has a $p = .06$; the male coefficient has a $p = .04$.

The coefficient on early income in the schooling regression is 0.19 years, which is not statistically significant at conventional levels ($p = .569$). The lack of a significant regression-adjusted association between early income and schooling is at odds with results presented in Duncan et al. (1998). The present analysis includes three different birth cohorts than Duncan et al. and the early income–schooling relation appears somewhat weaker for the new cohorts. A more interesting difference is that Duncan et al. assessed completed schooling by age 20—a kind of "on time" schooling measure. We tested several alternative schooling specifications, including completed schooling by age 21, on-time high school graduation (by age 18 or 19), had dropped out of high school as of age 21, and had attended some college as of age 21. In the case of completed schooling by age 21, we found that the coefficient on early income was 0.338 and statistically significant ($p < .05$). Further, when examining a specification that includes four time periods (prenatal through ages 2, ages 3 through 5, ages 6 through 10, and ages 11 through 15), the coefficient on age 3 through 5 was significant both for completed schooling by age 21 (0.399) and for on-time high school graduation (marginal probability effect from a logistic regression of 0.182). So it appears that early income may matter more for the on-time completion of schooling by the end of adolescent than for the sporadic increases in schooling that often occur later.

Results for the control variables in the completed schooling regression mirror past research, with Black people (adjusted for socioeconomic status and other controls), females, children born first, into intact or smaller families, or born to older mothers, more educated parents, greater household head expectations at birth or greater household head risk avoidance, obtaining more schooling. Few of these controls have persistently significant coefficients across all of the attainment-related outcomes in Table 2.

The marginal (probability change) effects from logistic spline models for poor health, high distress and overweight, and OLS results for BMI are shown in Table 3 and show scattered income effects in middle childhood and adolescence, but not early childhood. In no case are increments to low income in later childhood stages estimated to have a statistically significant impact on any of the health outcomes.

Table 4 presents marginal effects for the behavioral outcomes for men (arrests and jail) and women (nonmarital childbearing). Here again, the early-childhood income segments are not statistically significant in any of these models. As in the case of the health, increments to low income in middle childhood and adolescence are never estimated to have a statistically significant impact on any of the behavioral outcomes.

Extensions to Main Analysis

We explored the robustness of our results in various ways, first by testing for sex and race interactions. We found no statistically significant interactions by sex. For the race interactions, the incarceration of Black men appeared to be significantly less sensitive to increments in early-childhood income than the incarceration of White men. Specifically, the coefficient, expressed as a marginal effect on the probability of occurrence, on White incarceration was 0.38 ($SE = 0.16$) and the Black difference was −0.36 ($SE = 0.16$).

In averaging early-childhood income over the 7-year interval between the prenatal year and fifth birthday, there is a danger that we are missing a narrower sensitive period of income effects. In Table 5, we present results from regressions that are identical to those in Tables 2–4 except that the prenatal to age 5 period is further divided into two segments—the prenatal and birth years and ages 1 through 5. A comparison of coefficients shows that point estimates of income effects for four of the five attainment-related outcomes are all larger when income is measured between ages 1 and 5 than earlier, although only in the case of completed schooling is the difference statistically significant.

The opposite is true of body mass—very early income appears to matter more than income after the birth year, a result explored in some depth in Ziol-Guest, Duncan, and Kalil (2009). This finding of the particular importance of income during the prenatal and birth years for adult BMI may support the ''fetal origins'' hypothesis.

A more technical concern involving the income measure is that it is pretax total family income. An after-tax measure might better capture a family's spending opportunities and constraints. We re-estimated our models using childhood income measures from which PSID-calculated federal income taxes had been subtracted. The results proved somewhat sensitive to outliers but were generally quite similar to those shown earlier.

Table 6 explores the robustness of the prenatal-to-age-5 low-income coefficients in two additional models. The coefficients and standard errors in the first column are identical to those presented in Tables 2–4. In the second column, we retain all of the control variables, but in this case maternal earnings have been subtracted from all three stage-specific income variables. This helps to address the problem that mother's earnings are a component of childhood income. Mothers' labor supply decisions have implications for the amount of time mothers can spend with their children and may be affected by how successful the child's development is viewed by the family. For earnings and annual work hours for which early income effects were statistically significant in Table 2, the new income coefficients are smaller but retain statistical significance.

Stage-specific income results presented in Carneiro and Heckman (2003, p. 120) employ a somewhat different specification than ours in which

†$p < .10$. *$p < .05$. **$p < .01$.

childhood income is characterized by permanent (i.e., all-childhood-year average) income and just the early-childhood component. In this case, the coefficient on the early income component shows the coefficient *difference* from permanent income. As shown in the last pair of columns in Table 6, we find that early income is significantly more predictive of earnings and work hours than is permanent childhood income.

One concern in these types of analyses is omitted variable bias, and one approach to deal with this concern is to conduct sibling difference models that capitalize on within-family variation (Johnson & Schoeni, 2007). We tested these models for the earnings and annual work hours regressions. Because of small sample sizes, precision is a problem. For earnings, the coefficient (standard error) on the lower income spline segment was 0.30 (1.08) compared to 0.52 (0.21) in the full sample and the higher income spline was 0.07 (0.09) compared to 0.14 (0.14). For annual work hours, the coefficient and standard error on the lower income spline was 1047 (969) compared to 507 (135) in the full analysis; whereas the higher income early-childhood coefficient in the sibling fixed effects model was −8 (78) compared to 20 (10) in the analysis presented in Table 2.

Given the interesting results for the log earnings models, we sought to explore mediational pathways by sequentially introducing the sets of predictors listed in the columns of Table 7. Controls for childhood maternal work hours and family composition had little impact on the key early-income coefficient. Because controls for work hours and family structure are not so much mediators as additional childhood controls that might be biasing our income estimates, we have not included them in our basic models owing to their potential endogeneity. Completed schooling accounts for very little of the income effect, which is hardly surprising given the weak links between early income and schooling (see Appendix A). The same explanation probably underlies the lack of a mediational role for the behavior and health measures. On the other hand, the inclusion of adult work hours reduces the early-income coefficient by 80%, which suggests that much of the earnings impact of early-childhood income operates through annual work hours rather than wage rate.

The importance of work hours in the link between early-childhood income and annual adult earnings suggests that childhood income should have a relatively small effect on *hourly* earnings in adulthood. When we used average hourly earnings after age 25 as a dependent variable in our standard full-control regression model, the coefficient on early-childhood income was small and statistically insignificant. We investigated the work hours effects further by estimating whether early-childhood income appeared to operate by reducing unemployment or time out of the labor force altogether as opposed to full versus part-time work. For both men and women, the income effects were the strongest for full versus less-than-full time work.

Conclusion

Our exploration of the role of economic deprivation early in childhood produced surprisingly strong associations in the case of two important adult attainments—earnings and work hours. These results complement those reported in Duncan and Brooks-Gunn (1997), who found stronger correlations between early-childhood income and childhood achievement than between early income and either childhood behavior or health.

One way of assessing the policy significance of our coefficients is to express our results in income increments that have been associated with past policy changes. With the EITC transferring as much as $4,800 to working families, we used $3,000 as a possible increment. The coefficients imply that a $3,000 annual increase in income between a child's prenatal year and fifth birthday is associated with 19% higher earnings and a 135-hr increase in work hours. Moreover, most of the childhood-income effects on earnings appear to be accounted for by differences in annual work hours, suggesting that the results for work hours are particularly important to understand. Apart from studies looking at adult "idleness" (Haveman & Wolfe, 1994), there is little work on the childhood determinants of full-time work.

One important policy issue is the persistence of these effects across adulthood. A supplemental earnings regression that included an interaction between early-childhood income and age at which adult earnings were measured (not shown in the tables) indicated that the 19% proportionate impact of early-childhood poverty did not change over the ages for which we are able to track the sample (ages 25–37), so we can safely assume that the childhood income impact persists for at least that 13-year period.

We end with the usual cautions regarding the causal interpretation of our income "effects." Among the many approaches to estimating the causal impacts of childhood income on adult outcomes, ours is more sophisticated than some but less sophisticated than others. We are the first study to link high-quality income data across the entire childhood period with adult outcomes measured as late as age 37.

The incomes we observe are determined, in part, by the actions of parents and other family members, which leave our analyses open to omitted-variable bias. Our list of variables controlling for conditions at the time of birth is extensive and ought to reduce a good deal of potential bias. More important, and unusual for studies such as ours, is that our estimates of the impacts of early-childhood income control for income in middle childhood and adolescence. As such, factors such as genetic influences are as likely to affect later and early-childhood income, and thus are controlled, in some degree, by our inclusion of income in other childhood stages. Nevertheless, the possibility of lingering omitted-variable bias remains.

From External Regulation to Self-Regulation: Early Parenting Precursors of Young Children's Executive Functioning

Annie Bernier
University of Montreal

Stephanie M. Carlson
University of Minnesota

Natasha Whipple
University of Montreal

In keeping with proposals emphasizing the role of early experience in infant brain development, this study investigated the prospective links between quality of parent–infant interactions and subsequent child executive functioning (EF), including working memory, impulse control, and set shifting. Maternal sensitivity, mind-mindedness and autonomy support were assessed when children were 12 to 15 months old ($N = 80$). Child EF was assessed at 18 and 26 months. All three parenting dimensions were found to relate to child EF. Autonomy support was the strongest predictor of EF at each age, independent of general cognitive ability and maternal education. These findings add to previous results on child stress-response systems in suggesting that parent–child relationships may play an important role in children's developing self-regulatory capacities.

Growing interest has emerged for the hypothesis that early relational experiences are closely related to child neurocognitive development (e.g., Nelson & Bloom, 1997). In fact, the compelling link between quality of parent–child relationships and child cognitive development is often presumed to be due to the interplay between genetic factors and the social environment in shaping early brain development (De Bellis, 2001; Schore, 1996). One aspect of cognitive development that depends heavily on brain maturation is executive functioning (EF). This term refers to the set of higher order cognitive processes that underlie flexible goal-directed behaviors, such as inhibitory control, working memory, planning, and set shifting (Garon, Bryson, & Smith, 2008; Hughes, 2002; Miyake, Friedman, Emerson, Witzki, & Howerter, 2000; Zelazo, Carter, Reznick, & Frye, 1997). While there is convincing evidence that variation within the normal range of EF has important implications for child social and cognitive functioning, research on the antecedents of individual differences in EF lags far behind. Based on the demonstrated experience-dependent maturation of the brain in infancy and on the close connections between EF and brain development (Zelazo, Carlson, & Kesek, 2008), this report examines the role of early parent–child relationships in the development of child EF.

EF in Children

Owing to the close connections between EF and the slow-developing prefrontal cortex (Stuss & Benson, 1986), it was long believed that EF developed in adolescence only (e.g., Golden, 1981). It has since been demonstrated that EF develops much earlier and can be assessed at preschool age (e.g., Carlson, Mandell, & Williams, 2004; Diamond, Barnett, Thomas, & Munro, 2007; Hughes, Dunn, & White, 1998; Zelazo, Müller, Frye, & Marcovitch, 2003) or even toddlerhood (Carlson, 2005; Hughes & Ensor, 2005). In fact, some aspects of EF probably emerge

as early as the end of the 1st year of life (Diamond & Goldman-Rakic, 1989), and individual differences assessed in toddlerhood are moderately stable into the preschool years (Carlson et al., 2004; Hughes & Ensor, 2007).

The feasibility of studying EF in children has led to the crucial finding that this set of self-regulatory processes shows meaningful variation within normally developing children of varying ages. One of the most robust findings is that EF is linked to children's theory of mind understanding concurrently, longitudinally, and cross-culturally (e.g., Carlson & Moses, 2001; Carlson et al., 2004; Chasiotis, Kiessling, Hofer, & Campos, 2006; Hughes & Ensor, 2005, 2007; Müller, Zelazo, & Imrisek, 2005; Perner, Lang, & Kloo, 2002; Sabbagh, Xu, Carlson, Moses, & Lee, 2006; Tardif, Wing-Chee So, & Kaciroti, 2007). Another set of findings indicates that EF is related to children's proficiency in mathematics and arithmetic (Blair & Razza, 2007; Bull & Scerif, 2001; Espy et al., 2004; van der Sluis, de Jong, & van der Leij, 2007). In addition, EF has been found to relate to reading ability (Clark, Prior, & Kinsella, 2002; van der Sluis et al., 2007), verbal and nonverbal reasoning (Carlson, Moses, & Breton, 2002; van der Sluis et al., 2007), academic achievement (Biederman et al., 2004; Kinsella et al., 1997), communication, and social skills (Clark et al., 2002), as well as social and moral competence (Kochanska, Murray, & Harlan, 2000; Kochanska, Murray, Jacques, Koenig, & Vandegeest, 1996) and emotion regulation (Carlson & Wang, 2007; Simonds, Kieras, Rueda, & Rothbart, 2007).

Research has thus provided compelling support for the idea that individual differences in EF are meaningful for child cognitive and socioemotional functioning. This stands in sharp contrast to how little we know about the mechanisms that underlie the development of such individual differences. In light of the close connections between EF and frontal brain development (for a review, see Zelazo et al., 2008), and given the increasingly documented impact of environmental input on children's brain development (Chugani et al., 2001; Marshall & Fox, 2004), we propose that the study of early parent–child relationships is likely to be useful in understanding individual differences in children's EF.

Parenting and Child EF

It is increasingly believed that early environmental experiences have a direct impact on brain development (De Bellis, 2001; Gunnar, Fisher, & the Early Experience, Stress and Prevention Network, 2006; Nelson, 2000). The first 2 years of life, especially, witness a spurt in brain growth characterized by overproduction of synapses (Nelson, Thomas, & de Haan, 2006). During this phase, experience is presumed to determine to a large degree which synaptic connections persist and which are selectively eliminated due to lack of use (Greenough & Black, 1992; Nelson & Bloom, 1997; Singer, 1995). General support for such an experience-dependent nature of brain development is provided by animal models (e.g., Gunnar et al., 2006; McEwen, 1999) as well as by the study of grossly inadequate environments, characterized by neglect or abuse (Chugani et al., 2001; Curtis & Cicchetti, 2007; De Bellis, 2001, 2005; Marshall & Fox, 2004; Rutter, O'Connor, & the English and Romanian Adoptee Study Team, 2004; Rutter and the ERA Research Team, 1998). These studies suggest that unfavorable environmental experiences are related to problematic brain development, on both structural (e.g., De Bellis, 2001) and functional levels (e.g., Rutter et al., 2004).

Conversely, it is proposed that favorable environmental experiences, especially those embedded within early caregiving relationships, may have a positive impact on brain development (Glaser, 2000; Nelson & Bloom, 1997; Schore, 1996, 2001). Reviewing studies on maternal care and neural development in animal populations, Francis and Meaney (1999) concluded that, "variations in maternal care that fall within the normal range . . . can still have a profound influence on development. One does not need to appeal to the more extreme conditions of abuse and neglect to see evidence for the importance of parental care" (pp. 132–133). Examining similar questions with human populations, Hane and Fox (2006) found that normative variation in quality of parenting among mother–infant dyads was related to different patterns of frontal electroencephalographic asymmetry in infancy. Hence, given its close connections to brain structures, early development of EF is one aspect of child cognitive development that appears likely to be susceptible to strong care giving influences. According to Glaser (2000), the orderly development of the frontal lobes, strongly implicated in EF, is dependent on "appropriate input and sensitive interaction with the primary caregivers" (p. 101). Given that prefrontal cortex is a slow-developing area, with neural density of the frontal lobes beginning to decline at only about 7 years of age (Huttenlocher, 2002), there is indeed a large window of plasticity during which caregiving can have a significant impact on the developing structures.

Similar claims are made at the functional level. For instance, Kopp (1982) suggested that early caregiving is a central mechanism in children's developing capacities for self-regulation, the hallmark of EF. In line with this, attachment researchers have often proposed that caregivers initially act as external regulators of the infant's rhythms and affect, gradually facilitating the child's increasing capacity to self-regulate (e.g., Grossmann & Grossmann, 1991; Hofer, 1995; Spangler, Schieche, Ilg, Maier, & Ackermann, 1994). This view is supported by several studies that found links between quality of care and child psychophysiological regulation (see Gunnar & Donzella, 2002, for a review). Parenting may thus be a crucial factor in the development of child EF. However, it may not be optimal to consider parenting as a unitary construct, as empirical research with both animal and human populations increasingly suggests that different dimensions of caregiving can have distinct contributions to child functioning (e.g., Hofer, 1996; Meins, Fernyhough, Fradley, & Tuckey, 2001; Moran, Forbes, Evans, Tarabulsy, & Madigan, 2008).

Carlson (2003) proposes three dimensions of parenting likely to favor the development of child EF: maternal sensitivity, scaffolding, and mind-mindedness. Sensitivity, which consists of appropriate and consistent responses to infants' signals, would provide them with successful experiences of impacting the social environment. Scaffolding, that is, offering children age-appropriate problem-solving strategies, is likely to yield successful experiences of problem-based learning. Finally, mind-mindedness, or the parent's tendency to use mental terms while talking to the child, is thought to offer children verbal tools with which to progress from being externally regulated to self-regulated. Hence, these three parental behaviors represent ways in which caregivers act as external regulators, which according to Harrist and Waugh (2002), serves to help children become gradually more self-regulating away from caregivers. However, each behavior also has distinctive features, and hence possibly distinct contributions to child EF. Sensitivity and scaffolding refer to what the mother does, while mind-mindedness refers to what she says to the child about inner states, and sensitivity and scaffolding are likely to be activated in distinct situations, that is, contexts of personal distress versus exploration, respectively.

The Present Study

Although animal studies have documented the impact of parental care on the development of prefrontal systems (Gunnar et al., 2006), human research is limited, pertaining mostly to highly inadequate caregiving. Accordingly, the main purpose of this report was to examine the prospective links between quality of early mother–infant interactions and child subsequent EF in a normative population. The measurement of mother–infant interactions proceeded along the three dimensions proposed by Carlson (2003): We assessed maternal sensitivity and mind-mindedness at 12 months and maternal autonomy-support, including scaffolding, at 15 months. Child EF was assessed at 18 and 26 months. It was expected that more favorable parenting, indicated by higher sensitivity, more mind-minded comments, and greater autonomy support during mother–infant interactions, would be associated with better child performance on EF tasks at both 18 and 26 months of age, above and beyond parental education and child cognitive functioning. A secondary aim was to continue the recent line of work that has allowed for reliable measurement of EF at increasingly younger ages (Carlson, 2005; Hughes & Ensor, 2005). Hence, while the timing of the second assessment was based on the fact that validated measures of EF start at 2 years of age, the first assessment was planned 6 months before this age to examine the feasibility of assessing earlier manifestations of EF. We thus developed EF tasks for 18-month-olds and examined their capacity to detect individual differences, as well as continuity between child performance at 18 and 26 months of age.

Method

Participants

Eighty middle-class mother–infant dyads (44 girls and 36 boys) living in a large Canadian metropolitan area participated in this study. Families were recruited from birth lists provided by the Ministry of Health and Social Services. Criteria for participation were full-term pregnancy and the absence of any known physical or mental disability or severe developmental delay in the infant. Family income varied from less than $20,000 CDN to over $100,000 CDN, with an average of $70,000 CDN. Mothers were between 19 and 44 years old ($M = 29.4$). Most (78.8%) had a college degree and 81.3% were Caucasian. All but seven were married or living with the child's father throughout data collection.

Procedure

The dyads took part in four visits, when the child was 12–13 (T1; $M = 12.9$), 15 (T2; $M = 15.5$), 18 (T3; $M = 18.3$), and 26 (T4; $M = 26.3$) months of age. Home visits were conducted at T1, T2, and T4, while T3 consisted of a laboratory visit. All visits lasted between 70 and 90 min. The first home visit was modeled after the work of Pederson and Moran (1995), and aimed at challenging the mother's capacity to divide her attention between several competing demands, thus reproducing the natural conditions of daily life when caring for an infant. Research tasks included a developmental assessment (the Bayley scales), a brief interview with the mother, a 10-min videotaped mother–infant free play, and questionnaires that mothers had to complete while the infant was *not* looked after or kept busy by the research assistants. Maternal sensitivity was assessed with the Maternal Behavior Q-Sort (MBQS; see below) based on observations made throughout this visit, and mind-mindedness was later coded from the videotaped play interaction. The second home visit was similar in length and structure to the first one. Mothers were asked to help their children complete two puzzles that were designed to be slightly too difficult for the infants, such that they would require some adult assistance to complete them. This interaction was videotaped and later coded for maternal autonomy-supportive behaviors. Other activities included an interview with the mother, free play, and questionnaires. The third visit took place in the laboratory. The EF tasks described below were administered, along with other child and dyadic activities not used in the present study. Finally, the fourth visit took place in the families' homes. Most of the visit consisted of the administration of the EF tasks described below, along with other child and dyadic activities not included in this report.

Measures

Parenting

Maternal sensitivity. Maternal sensitivity was assessed using the MBQS (Pederson & Moran, 1995), a 90-item measure designed to assess the quality of maternal behaviors during in-home mother–infant interactions. The observer noted maternal behaviors throughout the visit and rated the MBQS immediately afterward based on the entire observation period. Items describing potential maternal behaviors are sorted into nine clusters, ranging from very similar to very unlike the observed mother's behaviors. The observer's sort is then correlated with a criterion sort representing the prototypically sensitive mother, which is provided by the developers of the instrument. Sensitivity scores thus vary from −1 (*least sensitive*) to 1 (*prototypically sensitive*).

The development of the MBQS is anchored in attachment theory and specifically in the descriptions of sensitive responsiveness provided by Ainsworth, Bell, and Stayton (1974). Pederson and colleagues (Pederson, Gleason, Moran, & Bento, 1998; Pederson & Moran, 1995; Pederson et al., 1990) have presented detailed descriptions regarding the development of the MBQS, as well as its validity and reliability. These authors' longitudinal studies show that the MBQS is useful in predicting multiple aspects of infant development. Moreover, the MBQS is significantly correlated with other assessments of maternal behavior, such as the Home Observation for Measurement of the Environment Inventory and the Ainsworth scales (see Pederson & Moran, 1995).

Previously trained home visitors performed their first few home visits with a more experienced colleague, and these visits were followed by a debriefing session aimed at reviewing the salient elements of the visit before scoring the MBQS. Following this training period, 25 home visits (31%) were conducted by two research assistants, who completed the MBQS independently. Agreement between the two raters' sorts was high, intraclass correlation (ICC) = .89.

Maternal mind-mindedness was assessed through a 10-min free-play sequence between mother and infant, in which the mother was instructed to play as she normally would, but with toys that were brought by the research team. Videotaped interactions were later coded by a trained assistant using Meins et al.'s (2001) coding system. Five categories of comments were assessed: (a) on the infant's mental state, such as thoughts, desires, knowledge (e.g., "You want this book"); (b) on mental processes (e.g., "You find this game difficult"); (c) on the infant's emotional engagement (e.g., "You had enough"); (d) on the infant's attempts to manipulate other people's thoughts (e.g., "You're making fun of me"); and (e) comments that involved the mother speaking for the infant (e.g., "See mom, it's easier this way''). Each comment was then coded as appropriate or inappropriate according to Meins et al.'s guidelines. The number of appropriate comments in each category were summed into a total score, which is used in all subsequent analyses.

A randomly selected 42.5% (*n* = 34) of videotapes were independently coded by a second trained rater. Interrater reliability was satisfactory, ICC = .89. Mind-mindedness has good convergent and predictive validity with measures of maternal sensitivity, mother–child attachment security, and child theory of mind understanding (Meins et al., 2001; Meins et al., 2002).

Maternal autonomy support. The notion of autonomy-support stems from Self-Determination Theory and refers to parental behaviors aimed at supporting children's goals, choices, and sense of volition (Grolnick & Ryan, 1989). Mother–infant dyads were asked to complete a challenging problem-solving task (two puzzles) together during a second home visit when the child was 15 months of age. Following the Grolnick, Frodi, and Bridges (1984) rating system, maternal behaviors were coded along two scales: verbal and nonverbal behaviors. In the current study, we further divided these scales into four categories reflecting the specific behaviors that constitute autonomy-support (Grolnick, Gurland, DeCourcey, & Jacob, 2002). The four Likert scales assess the extent (1–5) to which the mother (a) intervenes according to the infant's needs and adapts the task to create an optimal challenge (equivalent to scaffolding); (b) encourages her child in the pursuit of the task, gives useful hints and suggestions, and uses a tone of voice that communicates to the child that she is there to help; (c) takes her child's perspective and demonstrates flexibility in her attempts to keep the child on task; and (d) follows her child's pace, provides the child with the opportunity to make choices, and ensures that the child plays an active role in the completion of the task. Given the intercorrelations among the four scales (ranging from .51 to .82), they were averaged into a total autonomy support score (α = .89). All videotapes were coded by the third author of this report, and 38 of the 80 (47.5%) interactions were independently coded by a second observer. ICC between coders for the total autonomy-support score showed excellent interrater agreement, ICC = .86.

Child EF: 18-Month Assessment

The earliest measurement guidelines currently available to assess EF start at 24 months (Carlson, 2005). However, neuropsychological testing suggests that certain aspects of executive functions begin to develop earlier, notably rule use and working memory. We thus developed two downward adaptations of EF tasks originally designed for 2-year-old children.

Hide the Pots (adapted from Hughes & Ensor, 2005 [Spin the Pots]; see also Uzgiris & Hunt, 1975 [Scale I, Search for Hidden Objects]). An attractive sticker was hidden in full sight of the child under one of three opaque pots of different colors. In the warm-up phase, no further action took place, and the child was immediately asked to retrieve the sticker where it was hidden. Three practice trials were conducted (one with each pot). This phase was intended to introduce children to what was expected. In the second phase, the experimenter also hid the sticker once under each pot, but the pots were covered with a blanket before the child was invited to find the sticker on each trial. The child thus had to hold the location of the sticker in memory, remove the blanket, and reach for the pot where the sticker was hidden. Scores consisted of the number of trials (0–3) where the child found the sticker on his or her first attempt.

Categorization (adapted from Carlson et al., 2004). We used only the first phase of the original reverse categorization task, because the reverse phase was found to be difficult even for older toddlers (Carlson, 2005). Children were taught a categorization rule whereby baby animals were sorted together in the ''baby box,'' whereas adult animals were placed into the ''mommy box.'' The experimenter used the first six animals (three adults and three babies) to show the child how to sort the toys, and then asked the child to sort the six remaining ones. As many children placed all six animals together in one box (and thus got three ''correct'' answers by accident), the score was computed as the number of dyads (e.g., mother and baby zebra) that were correctly sorted separately by the child (0–3).

Child EF: 26-Month Assessment

The tasks conducted at 26 months were chosen based on Carlson's (2005) measurement guidelines with the aim of maximizing detection of individual differences in three dimensions of EF: working memory, inhibitory control, and set shifting.

Spin the Pots (Hughes & Ensor, 2005). Children were asked to search for stickers that were hidden in opaque pots, subsequently covered and rotated. Six stickers and eight pots of very different visual appearances were used. Each time a sticker was found, the pots were covered and rotated again. The score was calculated as 16 minus the number of errors made (i.e., looking under a pot in which no sticker had been hidden or perseverative looking).

Delay of Gratification (Kochanska et al., 2000). The experimenter placed a present under a transparent cup and asked children to wait until she rang a bell before retrieving it. Four trials were conducted, where the child had to wait 5, 10, 15, and then 20 s. Scores were the number of seconds waited on each trial.

Shape Stroop (Kochanska et al., 2000). Children were first shown six cards depicting three small and three large fruits, and were asked to point to each in turn to ensure they knew the names and sizes of the fruits (e.g., ''Show me the big apple''). They were then shown three cards each depicting one of the small fruits embedded in one of the larger ones, and asked to point to each of the small fruits in turn (e.g., ''Show me the *small* banana''). The score consisted of the number (0–3) of small fruits correctly pointed to.

Baby Stroop (adapted from Hughes & Ensor, 2005). Children learned a rule for feeding two dolls, feeding the ''mommy'' doll with a larger spoon and the baby doll with a smaller spoon. As soon as the child clearly understood the rule, it was reversed such that the larger doll had to be fed with the smaller spoon, and vice versa. Scores thus ranged from 0 to 2.

At both T3 and T4, administration of the EF tasks was videotaped for later coding. Because we were interested in individual differences rather than group patterns, EF tasks were administered in fixed order.

Child Cognitive Ability

In order to tap into what is unique to EF beyond general cognitive functioning, we used the Mental Development Index of the Bayley Scales of Infant Development (MDI; Bayley, 1993) at 12 months. The MDI is a well-standardized test of cognitive development for children aged 1–42 months, which shows predictive validity with respect to later verbal and cognitive performance (e.g., Lemelin, Tarabulsy, & Provost, 2006). A total of 23 protocols (29%) were double-coded by independent raters (using the video recording of the administration). ICC between raters' MDI scores suggested good reliability, ICC = .85.

Results

Preliminary Analyses

Table 1 presents descriptive statistics for all parenting and EF variables. The three parenting variables showed excellent variability (note that sample size varies slightly due to technical difficulties with certain videotapes). EF tasks also showed adequate

Table 1
Mean, Standard Deviation, and Range for All Parenting and Executive Functioning (EF) Measures

Variable	*N*	Mean	Standard deviation	Observed range	Theoretical range
Parenting					
Maternal sensitivity	80	0.59	0.33	−0.60 to +0.86	−1.0 to +1.0
Maternal mind-mindedness	74	14.58	8.71	0–39	0–N/A
Maternal autonomy support	77	3.28	1.13	1–5	1–5
Child EF 18 months					
Hide the Pots	80	1.22	0.91	0–3	0–3
Categorization	80	0.61	1.17	0–2	0–3
Child EF 26 months					
5-s delay	80	4.67	0.95	0–5	0–5
10-s delay	80	8.99	2.36	0–10	0–10
15-s delay	80	11.64	5.17	1–15	0–15
20-s delay	80	14.08	7.78	1–20	0–20
Spin the Pots	80	10.45	3.41	4–16	4–16
Shape Stroop	80	1.50	1.19	0–3	0–3
Baby Stroop	80	0.37	0.66	0–2	0–2

variability, although Categorization at 18 months and Baby Stroop at 26 months were negatively skewed, whereas the 5- and 10-s Delay of Gratification trials were positively skewed.

The two EF tasks at 18 months of age were unrelated to one another, $r = .11$, *ns*. These tasks were thus considered separately in all subsequent analyses. Table 2 shows the intercorrelations between EF scores at 26 months. In line with previous studies of EF in toddlers (e.g., Carlson et al., 2004; Hughes & Ensor, 2005), scores were mildly to moderately correlated. They were submitted to a principal component analysis, which yielded a two-factor solution (Eigen values > 1.0) representing 64.7% of the total variance. These two factors were submitted to a principal axis rotation (oblimin). Factor loadings for 10-s delay (.85), 5-s delay (.83), 15-s delay (.79), and 20-s delay (.71) suggest that the first factor taps impulse control, whereas the second factor appears to represent working memory, set shifting, and inhibitory control (Conflict EF): Spin the Pots (.82), Baby Stroop (.67), and Shape Stroop (.59). No cross-loadings (above .25) were observed, and the correlation between the two factors was .32. Given that the factor structure was very clear empirically and reproduced the two dimensions of Impulse Control and Conflict previously identified with young children (Carlson & Moses, 2001; Carlson et al., 2004), two averaged standardized scores were computed and used in further analyses. Impulse Control and Conflict were moderately correlated, $r = .28$, $p < .05$.

We next examined whether sociodemographic variables (child gender, number of siblings, maternal and paternal age and education, and family income) or child cognitive ability were related to EF performance at 18 and 26 months of age. Two relations reached significance at 18 months: Children of more educated mothers ($r = .22$, $p < .05$) and children who had higher mental development scores on the Bayley ($r = .24$, $p < .05$) performed better on Hide the Pots. Maternal education and child overall cognitive functioning (Bayley scores; $r = .17$, $p < .10$) were thus used as covariates in all further analyses pertaining to EF at 18 months. The analyses revealed no significant associations between the two EF dimensions at 26 months and sociodemographics (all *r*s < .18, *p*s > .10). However, child cognitive functioning was positively related to both EF dimensions: Impulse Control ($r = .28$, $p < .05$) and Conflict EF ($r = .25$, $p < .05$). We thus covaried cognitive functioning in all subsequent analyses involving EF at 26 months. Age was unrelated to EF performance, which was expected given the restricted age range at each time point. Child age was therefore not retained as a covariate in the main analyses.

Table 2
Intercorrelations Among Executive Functioning Scores at 26 Months

	10 s	15 s	20 s	Spin the Pots	Shape Stroop	Baby Stroop
5 s	.59***	.51***	.28*	.06	.22†	.10
10 s	1.00	.60***	.50***	.03	.19	.09
15 s		1.00	.63***	.11	.21†	.10
20 s			1.00	.24*	.28*	.12
Spin the Pots				1.00	.33**	.22†
Shape Stroop					1.00	.19
Baby Stroop						1.00

Note. 5 s = 5-s delay; 10 s = 10-s delay; 15 s = 15-s delay; 20 s = 20-s delay.
$^{\dagger}p < .10$. $^{*}p < .05$. $^{**}p < .01$. $^{***}p < .001$.

In line with their definitions as distinct aspects of one global construct, the three parenting dimensions were mildly intercorrelated: sensitivity and mind-mindedness ($r = .36$, $p < .01$), sensitivity and autonomy support ($r = .26$, $p < .05$), and mind-mindedness and autonomy support ($r = .38$, $p < .01$). These three dimensions were thus retained as separate scores.

Main Analyses

We first examined whether our adaptations of tasks for 18-month-olds tapped into early manifestations of EF by examining longitudinal stability at 18 and 26 months of age. The results showed that Hide the Pots at 18 months was related to both EF dimensions at 26 months (Impulse Control: $r = .28$, $p < .05$; Conflict: $r = .25$, $p < .05$), while Categorization was associated with later performance on Conflict only, $r = .24$, $p < .05$.

Table 3 presents the bivariate correlations between the three parenting dimensions and child performance on the two EF tasks at 18 months, as well as the partial correlations when accounting for maternal education and child cognitive functioning. Results indicated that child performance on Hide the Pots was related to all three parenting dimensions, but marginally so in the case of maternal sensitivity. Categorization was related to autonomy support. As expected, relations were positive in all cases.

We next examined relations between the parenting dimensions and child performance on the two EF dimensions at 26 months. Table 4 presents

Table 3

Bivariate (and Partial) Correlations Between the Three Parenting Dimensions and Child Performance on the Two EF Tasks at 18 months

EF task	Maternal sensitivity	Maternal mind-mindedness	Maternal autonomy support
Hide the Pots	.20† (.18)	.35** (.33**)	.38** (.39**)
Categorization	.08 (.15)	.04 (.04)	.25* (.30*)

Note. Numbers vary between 74 (mind-mindedness) and 80 (sensitivity). Partial correlations while controlling for maternal education and child cognitive functioning are shown in parentheses. EF = executive functioning.
†$p < .10$. *$p < .05$. **$p < .01$.

Table 4

Bivariate (and Partial) Correlations Between the Three Parenting Dimensions and Child Performance on the Two EF Dimensions at 26 Months

EF dimension	Maternal sensitivity	Maternal mind-mindedness	Maternal autonomy support
Impulse Control	.07 (.03)	.22† (.19)	.13 (.10)
Conflict	.25* (.26*)	.23† (.18)	.31* (.32*)

Note. Numbers vary between 74 (mind-mindedness) and 80 (sensitivity). Partial correlations while controlling for child cognitive functioning are shown in parentheses. EF = executive functioning.
†$p < .10$. *$p < .05$.

the bivariate correlations as well as the partial correlations when holding child cognitive functioning constant. All three parenting dimensions predicted later Conflict EF (although the relation with mind-mindedness was marginally significant only). Impulse Control was marginally related to maternal mind-mindedness, but this relation became nonsignificant when accounting for child cognitive functioning.

In summary, autonomy support was found to relate to three of four EF measures, that is, both 18-month tasks and Conflict at 26 months. In all cases, these relations held when controlling for potential confounds that were measured. Maternal sensitivity was associated with Conflict at 26 months and tended to relate to Hide the Pots at 18 months, although this latter relation became nonsignificant when controlling for potential confounds. Finally, mind-mindedness was significantly related to Hide the Pots at 18 months and marginally associated with both EF dimensions at 26 months, but these two latter associations did not hold over and above shared variance due to child cognitive functioning.

Table 5

Summary of Regression Analyses Predicting Child Performance on Hide the Pots at 18 Months

Block	R^2	ΔR^2	*F* change	β
1. Maternal education				.16
Child cognitive functioning	6.4%	6.4%	1.78*	.18
2. Maternal education				.04
Child cognitive functioning				.10
Autonomy support				.35*
Mind-mindedness	23.9%	17.5%	5.77**	.15

Note. $N = 74$.
*$p < .05$. **$p < .01$.

Note that in all cases where either maternal sensitivity or mind-mindedness related significantly to child EF, autonomy support related to the same EF index. We thus ran regression analyses to decipher the common and unique contributions of each parenting dimension to the variance in indices of EF that related to more than one parenting dimension (i.e., Hide the Pots at 18 months and Conflict EF at 26 months). Only those control and parenting variables that were significantly related to the EF index of interest were entered in each regression equation. Table 5 presents the results of the first hierarchical regression analysis predicting child performance on Hide the Pots. Maternal education and child cognitive functioning were entered in a first block, followed by mind-mindedness and autonomy support in a second block. Table 5 shows that the model predicted 23.9% of the variance in Hide the Pots, $F(4, 74) = 3.65$, $p < .01$, with parenting contributing a unique 17.5% ($p < .01$) over and above what is explained by maternal education and child cognitive functioning. The regression coefficients indicate that while autonomy support was uniquely related to child performance on Hide the Pots when mind-mindedness was accounted for ($\beta = .35$, $p < .05$), mind-mindedness did not relate to Hide the Pots when autonomy support was accounted for ($\beta = .15$, *ns*). Note that this pattern of results is consistent with statistical mediation; we return to this in the Discussion.

Table 6 presents the results of the second hierarchical regression analysis with Conflict EF at 26 months as the dependent variable. Child cognitive functioning was entered in a first block, followed by maternal sensitivity and autonomy support in a second block. The overall model was significant, $F(3, 77) = 2.89$, $p < .05$, explaining 16.4% of the variance of child performance on Conflict. A unique 10.1% ($p < .05$) was explained by parenting above and beyond child cognitive functioning.

Table 6

Summary of Regression Analyses Predicting Child Performance on Conflict EF at 26 Months

Block	R^2	ΔR^2	F change	β
1. Child cognitive functioning	6.3%	6.3%	3.11*	.25*
2. Child cognitive functioning				.19
Autonomy support				.25*
Sensitivity	16.4%	10.1%	3.59*	.14

Note. $N = 77$. EF = executive functioning.
*$p < .05$.

Quite similar to what was found with Hide the Pots, only autonomy support remained uniquely related to Conflict in the final model (β = .25, $p < .05$).

In a last step of this analysis, we examined whether parenting predicted EF at 26 months over and above stability in EF between 18 and 26 months. Given its clearer connections to EF at 26 months, we used Hide the Pots as the baseline 18-month EF index. Two regression analyses were conducted, one on Conflict as the dependent variable and one on Impulse Control. Each equation consisted of 18-month Hide the Pots and child cognitive functioning in a first block, followed by all three parenting dimensions in a second block. Analyses revealed that parenting did not contribute to changes in Impulse Control (4.3%, *ns*) but marginally predicted Conflict after accounting for longitudinal stability between 18 and 26 months and child cognitive functioning, 12.4% ($p < .10$). Contrary to expectations, however, this trend was not attributable to autonomy support (β = .16, *ns*) or sensitivity (β = .10, *ns*), but rather to mind-mindedness (β = .32, $p < .05$). Hence, while autonomy support was related to EF at both 18 and 26 months, mind-mindedness better explained increases in child performance between these two ages.

Discussion

The main purpose of this study was to investigate the prospective links between quality of parent–infant interactions and subsequent child EF. It was expected that higher quality parenting would predict better child EF performance at both short-term (3–6 months) and long-term (14 months) follow-ups. The results lend general support to this hypothesis. We found that mothers who were more sensitive with their 12-month-old child had children performing better on Conflict EF at 26 months. Their children also tended to perform better on working memory at 18 months, but this trend did not hold above the controls. Children whose mothers were more mind-minded when they were 12 months old performed better on working memory at 18 months, and tended to perform better on both Conflict and Impulse Control at 26 months, although these two latter trends did not hold when controlling for child cognitive functioning. However, mind-mindedness was related to changes in child performance between 18 and 26 months. Finally, mothers who were more autonomy supportive when their child was 15 months of age had children performing better on working memory and categorization at 18 months as well as on Conflict EF at 26 months. These latter findings held up over the controls.

These results provide support for the assumption that caregiving is involved in children's developing self-regulatory abilities (Hofer, 1995; Kopp, 1982) and suggest that the influence of parenting on the development of children's self-regulation can be observed not only on psychophysiological dimensions (Gunnar & Donzella, 2002) but also in the behavioral and cognitive domains. It remains to be seen whether the results found here suggest that early caregiving impacts brain structures involved in EF or indicate that parenting provides the child with the social context in which to practice emerging regulatory skills. These two possibilities, however, are not mutually exclusive and in fact, it is likely that a transactional process involving both is at play. It has been argued (e.g., Kraemer, 1992) that the effects of early caregiving on brain development, observed in animal studies and samples of maltreated children, may be observable also with normally developing infants. Such an influence could be attributable to the impact of parenting on child stress-response systems (Gunnar et al., 2006). The ensuing orderly development of frontal brain areas would favor the emergence of executive functions, allowing the child to regulate behavior more effectively at an early age. This emerging self-regulation may contribute to the maintenance of harmonious parent–infant interactions, in turn providing the child with a context favorable to increased self-regulation and possibly contributing further to brain development. Hence, early parenting may impact the process both by affecting the child's developing neurobiological structures and through the social environment provided to the child, and bidirectional effects between parenting and child EF are likely.

This is among the first studies to document links between early parent–child relationships and later child EF. In fact, extremely little is known about any antecedents of child EF, besides intrinsic factors such as child cognitive functioning (e.g., Carlson et al., 2004; Hughes & Ensor, 2005) and more distal factors such as socioeconomic status (SES; e.g., Mezzacappa, 2004). Hughes and Ensor (2005) examined relational factors and found that although quality of parenting was positively related to child EF in 2-year-olds, this relation did not hold after accounting for child age and verbal ability. The difference in results between their study and ours is particularly intriguing given that in both studies, great care went into the assessment of parenting, using both live observation and videotaped interactions in a variety of contexts, and multi faceted coding systems. In addition, our prospective design constituted a stringent test, making shared method variance especially unlikely to inflate the results. One explanation for the discrepant findings may relate to the nature of the samples: While our sample was predominantly middle-class, most families in Hughes and Ensor's sample were from lower SES backgrounds. Growing evidence suggests that the impact of caregiving on child outcomes may vary according to the social conditions of the dyad (see, e.g., Bernier and Meins's, 2008, analysis of parenting and attachment in low- vs. high-risk samples). One may speculate that in certain low-SES families, factors such as family chaos or parenting stress may limit the opportunities for joint cognitive activity, while the presumably lower stress experienced by middle-class families may leave more room for competent caregiving to foster development of the child's neural structures and self-regulatory capacities.

The clearest finding from this study is that autonomy support is the aspect of parenting that was most robustly related to age-specific indices of child EF. Autonomy support consists mainly of scaffolding, respecting the child's rhythm, and ensuring that he or she plays an active role in successful completion of the task. One can easily see how this set of behaviors is likely to provide the child with a sense of accomplishment and self-efficacy (cf. Bandura, 1997). That autonomy support would favor the emergence of child EF thus appears sensible, and we would argue that this is likely to be a robust finding. As well, it is possible that the autonomy support measure, which involved externally guided problem solving, provided a more direct contribution than other parenting qualities to self-guided problem solving that was required on the EF tasks administered later. In fact, our results complement the large literature on scaffolding, a key aspect of autonomy support, which has often been found to impact other aspects of child cognitive development such as language and problem-solving competence (e.g., Landry, Garner, Swank, & Baldwin, 1996; Landry, Smith, Swank, & Miller-Loncar, 2000).

In terms of the respective contributions of the different indices of parenting, however, one needs to take into account the methodological parameters of this study before drawing firm conclusions. Our results would appear to suggest that autonomy support not only relates more consistently to child EF than maternal sensitivity and mind-mindedness but also that it is responsible for most links found between child EF and either sensitivity or mind-mindedness. Recall that the regression analyses revealed that when two parenting dimensions were entered concurrently to predict an age-specific aspect of child EF, we did not find additive contributions, but rather that autonomy support remained the only significant predictor when either sensitivity or mind-mindedness was accounted for. A possible explanation is that this pattern of results, consistent with a statistical mediation, does indeed reflect true mediation. It stands to reason that a mother who is skilled at interpreting her child's signals correctly and responding appropriately (sensitivity), or is well aware of her child's mental processes while interacting with him or her (mind-mindedness), is well equipped to provide the child with an autonomy-supportive environment characterized by appropriate scaffolding, perspective taking, and respect for the child's rhythm in problem solving. However, the design of the current study does not permit us to rule out an alternative, methodological explanation. Autonomy support was assessed closer in time to EF than sensitivity and mind-mindedness (at 15 months vs. 12 months). Thus, the fact that autonomy support appeared to mediate the relations between sensitivity or mind-mindedness and child EF might also be attributable to different degrees of temporal proximity.

When predicting increments in EF performance, we found a slightly different picture: Mind-mindedness remained the only significant predictor of 26-month Conflict EF after accounting for child cognitive functioning, 18-month EF, and the other parenting indices. Combined with the finding that autonomy-support is related to both 18- and 26-month EF performance, this suggests that while autonomy support accounts for stability in EF performance, mind-mindedness rather accounts for changes between these two age periods. However, given that regression coefficients can be quite sensitive to the inclusion of correlated predictors in the equation, one should probably interpret the findings cautiously. While these analyses reaffirm the role of parenting in the *development* of EF through an especially stringent test, they also highlight the need for replication in larger samples before drawing firm conclusions on the role of specific aspects of parenting in changes and stability in EF. Similarly, given that part of what is observed with the Bayley scales may be presumed to be executive in nature, one may speculate that the analyses controlling for the MDI may actually be underestimating the predictions from parenting variables.

Nonetheless, the findings with mind-mindedness appear to suggest that parent attunement and talk about the child's mental states can build on basic levels of EF that were created, in part, by autonomy-supportive parental behavior, and give the child verbal tools to expand further on emerging regulatory abilities. This is speculative however, and teasing apart the true contributions of distinct aspects of caregiving to the development of child EF will necessitate assessment of different parenting indicators under methodologically equivalent conditions (including delay with subsequent assessment of EF). As well, research with higher risk samples may yield more variation in the lower spectrum of all three caregiving indicators, thus providing more power to detect links to child EF.

An important connection to previous research concerns the concept of effortful control (Blair & Razza, 2007; Kochanska et al., 1996; Kochanska et al., 2000; Rueda, Posner, & Rothbart, 2005). Whereas EF has its origins in neuropsychological research, effortful control refers to temperamentally based differences in the control of attention (Rothbart, 1989). Based on previous work suggesting that Kochanska's tasks provided excellent measurement of individual differences in EF (Carlson, 2005), we used some of those procedures at 26 months. Using a battery of effortful control tasks at 22 and 33 months, Kochanska et al. (2000) found that maternal responsiveness at 22 months, but not at 9 nor 14 months, was related to child effortful control at both 22 and 33 months. Our research shares comparable findings, suggesting that parenting assessed between 9 and 15 months does not relate to impulse control (this study) or effortful control (Kochanska et al., 2000). However, Kochanska et al.'s positive findings with responsiveness assessed at 22 months suggest that this may change as the child gets older or, again, that more proximal measurement points are more strongly related. More longitudinal studies of parenting are needed to shed light on concurrent and prospective links between parenting and child EF at different ages. Furthermore, and in line with recent research, one might speculate that caregiving and child temperament interact in influencing the development of certain aspects of EF (see Crockenberg & Leerkes, 2006; Kochanska, Aksan, & Joy, 2007, for recent examples of such moderating influences on other child outcomes).

A secondary aim of this study was to develop EF measures for younger age groups. We simplified tasks originally designed for 24-month-olds and examined their capacity to detect variation as well as their relations to validated measures at 26 months and to parenting. Despite their low intercorrelation, both 18-month tasks (Hide the Pots and Categorization) were found to be positively related to Conflict at 26 months, and Hide the Pots was associated with later Impulse Control as well. The magnitude of these longitudinal links was similar to that reported by Hughes and Ensor (2007) between 2 and 3 years of age. This tentatively suggests that both tasks may be valid assessments of early manifestations of EF. However, one may also argue that Hide the Pots is more valid than the sorting task, given that it showed more variability, clearer connections to 26-month tasks, and more compelling links with parenting. Overall, the current adaptation of Spin the Pots can reasonably be considered as a useful first step in developing EF measures for 18-month-olds, but more research is needed before one can confidently conclude that either of our 18-month tasks can be used by itself as an indicator of early EF.

This study provides among the first longitudinal evidence that early parent–child relationships may be useful in understanding the origins and growth of individual differences in child EF. Given that the associations found were derived from observations of different individuals (parent behavior vs. child performance), assessed in different contexts and at different times (with delays of up to 14 months), one can reasonably assume that the links are conceptually robust. Given that parenting contributed substantial additional variance in child EF above its well-documented precursors (child cognitive functioning and maternal education), we argue that further exploration of parenting is likely to be a fruitful path for research on childhood EF. However, intriguing questions remain, for instance, with respect to which aspects of parenting contribute to which components of EF, at which ages, and via which neural and social mechanisms. Given the impressive range of child cognitive and socioemotional outcomes related to EF, the search for the social contexts most likely to favor its development is an important task for future research.

To further the understanding of the effects of early experiences, 9-month-old infants were observed during a frustration task. The analytical sample was composed of 348 linked triads of participants (adoptive parents, adopted child, and birth parent[s]) from a prospective adoption study. It was hypothesized that genetic risk for externalizing problems and affect dysregulation in the adoptive parents would independently and interactively predict a known precursor to externalizing problems: heightened infant attention to frustrating events. Results supported the moderation hypotheses involving adoptive mother affect dysregulation: Infants at genetic risk showed heightened attention to frustrating events only when the adoptive mother had higher levels of anxious and depressive symptoms. The Genotype × Environment interaction pattern held when substance use during pregnancy was considered.

The independent contributions of genetic and environmental influences to child behavior have been well established over the past several decades using behavioral genetic designs (Reiss, Neiderhiser, Hetherington, & Plomin, 2000; Rutter, 2006). This body of research has indicated moderate genetic effects on most dimensions of externalizing behavior (Rhee & Waldman, 2002). Emanating from and building upon this work, there is a burgeoning body of evidence from behavioral and molecular genetic studies suggesting that environmental factors moderate or mediate genetic influences on

problem behaviors. Studies of Genotype × Environment (G × E) interaction help to illustrate how inherited characteristics render some individuals more susceptible to the negative or positive effects of specific environments (Moffitt, Caspi, & Rutter, 2005). This line of investigation is important in helping to identify mechanisms whereby specific environmental processes might offset or exacerbate genetic risk, thereby suggesting potential targets for preventive interventions. Most of the published studies in this area, however, have used retrospective measures of the environment or have studied environmental processes in middle childhood and beyond (Caspi et al., 2002; Feinberg, Button, Neiderhiser, Reiss, & Hetherington, 2007). Such approaches miss the opportunity to capture environmental experiences during the early childhood developmental period, which has been found to be malleable to preventive interventions (Olds, 2002; Shaw, Dishion, Supplee, Gardner, & Arnds, 2006). In this study, we examine specific genetic and family environmental processes on a known precursor of externalizing behavior: infant heightened attention to frustrating events (Crockenberg, Leerkes, & Barrig Jo, 2008).

Connection Between Attention to Frustration and Subsequent Externalizing Behavior

The focus on infant attention to frustrating events, which has known links to subsequent externalizing behavior, was selected because infants are not developmentally capable of engaging in behaviors typically captured by standard definitions of externalizing behavior (e.g., cheating, lying, or directed aggression). Further, temperamental characteristics such as anger do not show a consistent relation with externalizing problems until 12–24 months of age (Blair, 2002; Lyons-Ruth, Easterbrooks, & Cibelli, 1997; Smeekens, Riksen-Walraven, & van Bakel, 2007). The behaviors involved in attention regulation undergo a developmental shift between 3 and 6 months of age (e.g., the acquisition of visual orientation skills and the ability to disengage visual gaze; Johnson, Posner, & Rothbart, 1991; Posner & Petersen, 1990), making infancy an ideal time to examine attentional processes. One aspect of attention—infant's attention to frustrating events (defined in this article as focus and persistence on a frustrating event)—has been examined in numerous studies during early childhood. Stifter and Braungart (1995) indicated that 5- and 10-month-olds were more likely to visually shift their attention away from a frustrating event when infant distress was decreasing, suggesting a regulatory role of infant ability to shift attention away from frustrating events. In addition, converging evidence from longitudinal studies has indicated a link between attentional focus on frustrating events and later externalizing problems.

In a longitudinal study of 5-month-old infants, Crockenberg et al. (2008) found that infants who failed to shift attention away from frustrating events (an arm restraint and a toy-removal task) exhibited increased aggressive behavior at 2½ years of age. Attention to frustration was defined by coder ratings of infant attempts to inspect the frustrating event and situation. The association between this infant behavior and later aggression was the strongest when mothers encouraged their child to look at the frustrating event, which is consistent with the notion that maternal regulation processes moderate pathways to externalizing problems. Crockenberg et al. suggested that attention to a frustrating event is the dominant response and that successfully looking away reflects the ability to adaptively manage frustration. Regulation characteristics of the mother might undermine the development of a child's capacity to shift attention away from frustrating events, inadvertently contributing to the development of externalizing problems. In the present study, we mirrored Crockenberg et al.'s work by utilizing a similar toy-removal task across repeated intervals and by coding for infant attention to the frustrating event and situation.

Although we are unaware of other studies that have employed toy-removal protocols to measure attention to frustrating events, several longitudinal studies have examined early childhood attentional problems using other methods and have found similar associations with subsequent externalizing problems. For example, Caspi, Henry, McGee, Moffitt, and Silva (1995) found that observer ratings of 3-year-olds' inability to modulate attention and lack of control were prospectively associated with externalizing problems in adolescence. Further, at 21 years of age, young children with these attention problems were more likely to be diagnosed with antisocial personality disorder (Caspi, Moffitt, Newman, & Silva, 1996). Tracing the pathways to externalizing problems earlier in development in two independent cohorts of low-income families, Shaw, Keenan, and Vondra (1994) and Shaw et al. (1998) observed mothers with their 12-month-olds during a task designed to elicit infant frustration behavior (i.e., high chair task). In both cohorts, boys who were higher on persistence in the face of caregiver unresponsivity at 12 months showed elevated rates of externalizing problems at age 2 and between ages 3 and 3½ based on observations and maternal ratings of disruptive behavior (e.g., noncompliance, aggression). These studies replicated earlier work by Martin (1981), who used the same high chair task and found remarkably similar results for boys from less disadvantaged backgrounds.

There is also evidence to indicate that at-risk children may have heightened states of arousal and reactivity (Fisher, Stoolmiller, Gunnar, & Burraston, 2007), which might cause them to focus on negative cues that typically invoke negative emotions such as anger (Shackman, Shackman, & Pollak, 2007). Consistent with this body of work, we hypothesize that, under conditions of frustration, infants at risk for externalizing problems will react with increased attention and persistence. The extent to which the early home environment and genetic factors jointly affect the development of attention to frustration has yet to be investigated; in this study, we extended prior work by focusing on genetic and environmental influences on infants' attention behavior during a frustration task.

Genetic Contributions to Externalizing Behavior

The results from twin and adoption studies on the heritability of externalizing behavior provide evidence that the externalizing behaviors of interest in the proposed study are genetically influenced. In a meta-analysis of 24 genetically informative studies on aggression, Miles and Carey (1997) found that genetic effects accounted for approximately 50% of the variance in aggressive behavior. More recently, in a meta-analysis of 51 twin and adoption studies of antisocial behavior, Rhee and Waldman (2002) found more modest genetic influences (41%). The findings from recent twin and adoption studies also point to genetic influences on attention deficit problems (Thapar, O'Donovan, & Owen, 2005), novelty seeking (Hiroi & Agatsuma, 2005), and the associations between novelty seeking, externalizing behavior, and substance use (Laucht et al., 2007). Although useful in identifying potentially heritable aspects of externalizing behavior, such findings provide little information about the mechanisms of development, how the phenotype might evolve across development, and how genetic aspects of externalizing behavior during adolescence and adulthood relate to the genetic aspects of infants' propensity for externalizing behavior.

The findings from life-course studies by Laucht and colleagues have provided information about possible mechanisms in this regard. In this work, novelty seeking was found to be associated with a polymorphism of the DRD4 gene (Laucht, Becker, El-Faddagh, Hohm, & Schmidt, 2005). In a longitudinal study from infancy to adolescence, Laucht, Becker, and Schmidt (2006) found that visual exploratory behavior (i.e., longer initial looking times) and a higher response decrement (i.e., habituation) in 3-month-olds was associated with novelty seeking in adolescence and the 7r DRD4 allele variant. This is one of the few areas where a genetically influenced characteristic has been shown to have different and specific phenotypic expressions across development, manifested as attention during early infancy and as novelty seeking (a form of externalizing behavior) during adolescence. Guided by this genetically informed work and the phenotypic work on the association between attention to frustration and later externalizing problems described earlier, we focused on infant attention to frustration to better understand the early mechanisms underlying the development of externalizing behavior.

Role of Parental Affective Dysregulation

According to Crockenberg et al. (2008), maternal behavior plays a key role in the development of a child's attention behavior and externalizing trajectories. One of the most well-documented risk factors during infancy of current and later externalizing problems is maternal depression (Campbell, Matestic, von Stauffenberg, Mohan, & Kirchner, 2007; Downey & Coyne, 1990). There is an extensive body of evidence to suggest that caregiver depression interferes with the ability to sensitively parent (Cicchetti, Rogosch, & Toth, 1998). Similarly, maternal anxiety has been shown to relate to problem behaviors in children, including anxiety and depression, attention deficit disorders, and oppositional defiant disorders (Meadows, McLanahan, & Brooks-Gunn, 2007). Thus, maternal affective dysregulation during infancy is commonly viewed as one of the strongest environmental predictors of child problems. The adoption design provides a unique opportunity to examine whether associations between caregiver affective state and child externalizing problems are found when family members are genetically unrelated.

Current Study

In this study, a prospective adoption design is employed to examine hypotheses regarding the environmental moderation of genetic risk for externalizing behavior. In this design, the infant adopted by nonrelative parents shares 50% of his or her segregating genes with each of the birth parents but none with the adoptive parents. Conversely, the adopted child shares 100% of the rearing environment with the adoptive parents but none of the rearing environment with the birth parents. As such, genetic influences can be inferred based on similarities between the child and the birth parent(s), and environmental influences can be inferred based on similarities between the child and the adoptive parents. This design strength results from the fact that children placed in nonrelative adoptive homes do not share genes with their caregivers; thus, genetic influences cannot account for associations often seen between the caregiving environment and child behavior.

To date, only one other prospective longitudinal adoption study has examined genetic and environmental effects on social processes during infancy: the Colorado Adoption Project (CAP; Plomin, DeFries, & Fulker, 1988). Although the CAP has yielded evidence of G × E interactions on social behaviors during later childhood (Hershberger, 1994; O'Connor, Caspi, DeFries, & Plomin, 2003), G × E interaction effects during infancy have not been published to date. In the present study, we built upon the methods of the CAP by collecting observational assessments of social processes in the adoptive family and by using a fine-tuned assessment protocol with birth parents that included multiple measures of each targeted social construct to increase the reliability of genetic indices. By using a theory- and research-guided approach to carefully match birth parents' social characteristics with hypothesized externalizing and internalizing child outcomes a priori (Leve et al., 2007), we sought to increase the likelihood that G × E interactions would be detected in those domains.

Guided by the research reviewed earlier, we formulated three hypotheses: (a) that genetic effects on pathways to externalizing behavior could be traced intergenerationally via the association between birth parent externalizing behavior and heightened infant attention to frustration; (b) that adoptive parent affective state (e.g., anxious or depressive symptoms) would relate to infant attention to frustration, with higher levels of anxiety and depression being associated with greater infant attention to frustration; and (c) that the affective state of the adoptive parents would moderate genetic influences on infant attention during a frustration task, increasing the association between birth parent externalizing problems and infant attention to frustration. Because substance use during pregnancy can confound genetic effects on development, we examined birth mother prenatal substance use in a secondary set of analyses.

Method

Participants

The sample consisted of participants in the Early Growth and Development Study (EGDS), an ongoing, longitudinal, multisite study of 361 linked triads of adopted children, adoptive parents, and birth parents. The primary goal of the EGDS is to examine the effects of G × E interaction and correlation on the social and emotional development of young children. The recruitment of participants occurred between 2003 and 2006, beginning with the recruitment of adoption agencies ($N = 33$ agencies in 10 states located in the Northwest, Mid-Atlantic, and Southwest regions of the United States). The participating agencies reflected the full range of adoption agencies in the United States: public, private, religious, secular, those favoring open adoptions, and those favoring closed adoptions. Each adoption agency appointed a liaison from their organization to assist with recruitment. The agency liaisons identified participants who completed an adoption plan through their agency and met the study's eligibility criteria: (a) the adoption placement was domestic, (b) the baby was placed within 3 months postpartum, (c) the baby was placed with a nonrelative adoptive family, (d) the baby had no known major medical conditions such as extreme prematurity or extensive medical surgeries, and (e) the birth and adoptive parents were able to read or understand English at the eighth-grade level. The study participants were representative of the adoptive and birth parent populations that completed adoption plans at the participating agencies during the same time period (Leve et al., 2007).

The analytical sample for this report consisted of 348 linked triads from the first wave of assessment from whom at least two of the three members of the triad had data on the variables used in this study. In addition, data from 105 birth fathers (BFs) are included. The children were 9 months old during the assessment, $M = 9.20$ ($SD = 0.55$ months). Four triads were excluded from subsequent analyses on the basis of infant age (i.e., 1 child was 6 months old, and 3 children were more than 12 months old). Forty-three percent of the children were female. The mean child age at the adoption placement was 3 days (*SD* = 5 days). The adoptive families were typically college-educated, middle-class families, and the mean ages of adoptive mothers (AMs) and fathers (AFs) were 37 and 38, respectively. Ninety-three percent of the AMs and 92% of the AFs were Caucasian; 4% of the AMs and 5% of the AFs were African American; 2% of the AMs and AFs were multiethnic; 1% of the AMs and AFs were Hispanic or Latino; and the remaining participants were not identified or were of other ethnic status. The adoptive parents had been married an average of 11.8 years (*SD* = 5.1 years), and 51% of the adoptive families had at least one additional child in the home at the time of the writing of this report. Information about which adoptive parent was the primary caregiver was not collected. The birth parents typically had high school or trade school education levels and household incomes under $25,000, and the mean ages of birth mothers (BMs) and BFs was 24 and 25, respectively. Seventy-eight percent of the BMs and 63% of the BFs were Caucasian; 11% of the BMs and 20% of the BFs were African American; 5% percent of the BMs and BFs were multiethnic; 4% of the BMs and 8% of the BFs were Hispanic or Latino; and the remaining participants were not identified or were of other ethnic status. There were no significant differences in demographic characteristics between the full EGDS sample and the participants in the analytical sample used in this report. Complete demographic information on the full EGDS sample regarding AM, AF, BM, and BF age, race, education, and income are presented in Leve, Neiderhiser, Scaramella, and Reiss (2008).

The study design included a birth parent in-person assessment between 3 and 6 months postpartum and an adoptive family in-person assessment when the child was 9 months old. The birth parent assessment was 2 hr long and was conducted in the home or in another convenient location; the adoptive family assessment was 2½ hr long and was conducted in the home. The participants were paid for their time. For the birth and adoptive parent assessments, the interviewers asked computer-assisted interview questions, and each participant independently completed a set of questionnaires. In addition, the adoptive parents were observed individually (and once conjointly) in a series of interaction tasks with their child. The birth and adoptive parent assessments were completed by separate teams of interviewers to prevent data sharing across members of the adoption triad. The interviewers completed a minimum of 40 hr of training, including a 2-day group session, pilot interviews, and videotaped feedback prior to administering interviews with study participants. All interviews were audio- or video-recorded, and feedback was provided by a trained evaluator for a random selection of 15% of the interviews to ensure adherence to the study's standardized interview protocols. Additional details on the EGDS study recruitment procedures, sample, and assessment methods can be found in Leve et al. (2007).

Measures

Genetic Risk for Externalizing Behavior

To estimate genetic risk for externalizing behavior, we administered three birth parent self-report measures considered to be indicators of externalizing behavior: lifetime alcohol, tobacco, and other drug (ATOD) dependence; delinquency; and novelty seeking.

ATOD dependence. ATOD dependence was measured using a modified version of the Composite International Diagnostic Interview–Short Form (CIDI–SF) Alcohol and Drug Dependence scales (Kessler, Andrews, Mroczek, Ustun, & Wittchen, 1998). The original CIDI–SF questions were modified for this study to pertain to lifetime use (rather than 12-month use) and to include a set of tobacco-dependence questions. The indicators of lifetime problem use of alcohol, tobacco, marijuana, and other drugs were then combined to form a composite ATOD-dependence score. Alcohol dependence was calculated as the sum of seven items from the CIDI–SF assessing alcohol-dependence symptoms in the past 12 months (BM: $\alpha = .82$; BF: $\alpha = .85$). For tobacco dependence, a 4-point scale was created using questions regarding past or current regular tobacco use and two dependence symptoms: 0 (*never used*), 1 (*past or current regular use but other dependence symptoms denied*), 2 (*one dependence symptom endorsed*), and 3 (*both dependence symptoms endorsed*). Marijuana dependence was calculated as the sum of seven CIDI–SF dependence items (BM: $\alpha = .85$, BF: $\alpha = .88$). Other drug dependence included the following eight substance classes: sedatives, tranquilizers, amphetamines, painkillers, inhalants, cocaine, heroin, and hallucinogens. More than half of the birth parents reported use of one or more of these substance classes. However, use within any specific substance class was relatively low (14%–26%). Therefore, we created dependence symptom scales for each substance class (based on the sum of CIDI–SF dependence items for that substance class; BM: α = .63–.97; BF: α = .74–.96). The other drug-dependence indicator was calculated by averaging the standardized dependence symptom scales across each substance class (BM: α = .85; BF: α = .83).

The ATOD dependence indicators were each standardized, and a composite ATOD-dependence score was created (BM: α = .72; BF: α = .71).

Delinquency. Delinquency was measured using the 38-item Elliot Social Behavior Questionnaire (Elliott, Huizinga, & Ageton, 1985). On this self-report delinquency scale, birth parents rated items reflecting their engagement in various delinquent behaviors (e.g., purposely damaged or destroyed property, purposely set a fire, carried a hidden weapon, or stole something). Items were summed to create a delinquency score (BM: α = .88; BF: α = .91). The scales were log-transformed to reduce skewness.

Novelty seeking. Novelty seeking was based on the 20-item Novelty Seeking subscale of the Temperament Character Inventory (BM: α = .73; BF: α = .68; Cloninger, Svaric, & Przybeck, 1993). This measure of general temperament and character is composed of 125 true or false items. Higher scores on the Novelty Seeking subscale indicate an exploratory and novelty seeking personality, impulsive decision making, quick loss of temper, and excitable, enthusiastic, easily bored, and ardent behavior.

Associations among the externalizing indicators. For the BMs, the three standardized indicators (ATOD dependence, delinquency, and novelty seeking) were significantly correlated (r = .28–.41, p < .001) and each loaded significantly on a one-factor solution (.76, .79, and .69, respectively), forming an internally consistent scale (α = .61). The BF indicators did not show the same level of internal consistency, with a nonsignificant correlation among one set of variables and a marginally internally consistent scale (α = .56). Still, the three indicators all loaded significantly on a one-factor solution (.73, .85, and .59, respectively). The three BM externalizing behavior indicators were used in structural equation modeling (SEM), and a factor score was created for use in graphing. A BF externalizing behavior factor score based on the 99 BFs with data on all three indicators was calculated and used in the BF analyses.

Adoptive Parent Affective State

Adoptive parent affective state was examined using the Beck Anxiety Inventory (BAI; Beck & Steer, 1993a) and the Beck Depression Inventory (BDI; Beck & Steer, 1993b). Anxiety symptoms were calculated as the sum on the 21-item BAI (AM: α = .76; AF: α = .74). Depressive symptoms were calculated as the sum of 20 items from the 21-item BDI (AM: α = .72; AF: α = .75); the suicidal ideation item was not administered in the present study to minimize situations where clinical follow-up would be necessitated. The anxiety and depressive scales were log-transformed to reduce skewness. The resulting scales were correlated for AMs (r = .48) and AFs (r = .54) but were not correlated between parents. Thus, we standardized the anxiety and depression scales for each parent based on the means. Higher scores indicated greater anxious and depressive symptoms.

Infant Attention During a Frustration Task

Infant attention to frustration was measured during a barrier task as part of the laboratory temperament assessment battery assessment protocols (Goldsmith & Rothbart, 1996). In this video-recorded task, the child is seated in a high chair while six trials are run in 30-s intervals, alternating between neutral trials (Trials 1, 3, and 5) and frustration trials (Trials 2, 4, and 6). During each neutral trial, the same stimulating toy is presented on a high chair tray to the infant for 30 s. On each frustration trial, a clear Plexiglas barrier is placed between the infant and the toy for 30 s so that the infant can readily see the toy but cannot touch it. The barricade task was selected because of its developmental appropriateness and its similarity to attention to frustration tasks used in other studies during infancy (Crockenberg et al., 2008).

Infant attention during each trial of the barricade task was coded from video-recorded data using the interest and persistence scale from the family interaction behavior codes (Dogan et al., 2005). This scale assesses a child's level of engagement with the toy provided in the task. The primary measure is the amount of time the child engages with or attempts to engage with the toy. It also includes the amount of interest the child initially displays in the toy during each interval. A child scoring high on interest shows attention to, focus on, and thorough attempts to explore the toy provided to him or her for an extended period of time. Trained coders rated infants on interest behavior during each of the six trials using a 9-point Likert-type scale: 1 (*not at all characteristic*) to 9 (*mainly characteristic*). Thirty-five percent of the infants were dual-coded by independent coders to establish reliability. Coder intraclass correlations ranged from .91 to .97 across the six trials, indicating high inter rater reliability.

A factor analysis with oblique rotation supported a two-factor solution and a distinction between the trial types; neutral trials loaded .76–.84 on one factor, while frustration trials loaded .77–.86 on a second factor (r between factors = .315, $p < .001$). Attention ratings were standardized at each trial. The measure of attention during neutral trials was calculated as the mean of standardized ratings on Trials 1, 3, and 5 ($\alpha = .71$), and attention during frustration trials was calculated as the mean on Trials 2, 4, and 6 ($\alpha = .76$). Attention during the frustration trials served as the dependent measure of interest for the current analyses; attention during the neutral trials was included as a control variable to take into account individual differences in general attention levels during neutral situations.

Additional Control Variables

Several additional control variables were included to control for phenomena noncentral to the study hypotheses.

Openness in adoption. To control for similarities between birth and adoptive families resulting from contact and knowledge between parties, we controlled for the level of openness in the adoption. We measured openness in adoption using a composite index of BM, BF, AM, and AF perceived openness using a 7-point scale: 1 (*very closed*) to 7 (*very open*). Interrater agreement was high (r range = .66–.81; Ge et al., 2008).

Child sex. Child sex was coded as 1 (*female*) or 2 (*male*).

BM prenatal ATOD use. Maternal prenatal ATOD use can confound estimates of the genetic influences related to substance use (such as our ATOD dependence measure, described above). Thus, prenatal ATOD use was included as a control variable in a secondary set of analyses. The BMs reported prenatal ATOD use on each of 10 substance classes (tobacco, alcohol, sedatives, tranquilizers, amphetamines, painkillers, inhalants, cocaine, heroin, and hallucinogens) using a pregnancy history calendar method developed for the study. The BMs were asked to identify key events throughout the pregnancy period (e.g., birthdays, holidays, and vacations) and to note them on a one-page life history calendar, which has been shown to be an effective and reliable tool for recording retrospective events and conditions (Caspi, Moffitt, Thornton, et al., 1996). The BMs then responded to questions about their substance use during the pregnancy period, using the calendar as a reference to facilitate recall.

For tobacco use, the BMs reported whether they had smoked cigarettes in the first, second, and/or third trimesters of this pregnancy using a yes or no format; 59.6% reported not smoking, and 26.2% reported smoking during all three trimesters. For the remaining substances classes, we used a 5-point scale for the 9-month pregnancy period: 0 (*never*) to 4 (*regularly or most days, or every day*). Few BMs reported more than rare alcohol use (5.4%) or any level of use within the other drug classes (ranging from 0.3% for hallucinogens to 16.4% for marijuana), but 27.0% of the mothers reported use of at least one of these substances. Given the skewed distributions of the use indicators, we considered a variety of rescaling options when constructing an overall scale. Dichotomizing all 10 indicators—0 (*no use*) or 1 (*any use*)—yielded an internally consistent scale, Cronbach's α (KR-20) = .67. Hallucinogen use was omitted during scale development due to low frequency but was included in the final scale because of face validity. The sum of dichotomous indicators was positively skewed and was therefore collapsed into a 5-point scale: 0 (*prenatal use of no substances*) to 4 (*prenatal use of four or more substances*).

Data Analysis Approach

The analyses were aimed at examining genetic, family environment, and Genotype × Family Environment effects on infant heightened attention during the frustration task. Significant correlations between an infant characteristic and a birth parent characteristic belonging to the same underlying construct were inferred to reflect genetic influences.

SEM using Mplus (Muthén & Muthén, 2006) was used to test whether BM externalizing behavior (a latent factor indexed by multiple indicators), AM and AF affective state (observed variables), and the interaction between them predicted infants' attention during the frustration trials (an observed variable). We tested the interactions involving AM and AF affective state separately, while controlling for the other adoptive parent's state (e.g., BM Externalizing × AM Affective State, controlling for AF affective state). Three control variables were included in the models: infant sex, openness in adoption, and infant attention during the neutral trials. In addition, we examined BM substance use during pregnancy in follow-up analyses to determine whether genetic influences were confounded by prenatal ATOD use.

All of the variables were standardized prior to modeling and used the maximum likelihood algorithm with robust standard errors (MLR; Muthén & Muthén, 2006) to derive parameter estimates in the presence of missing data. Given the lack of established fit statistics for models involving statistical interaction with latent variables, we followed a series of steps to test these models. First, to test whether the model provided an adequate fit without the interaction term, we computed an MLR chi-square (asymptotically equivalent to Yuan–Bentler T2 χ^2; Muthén & Muthén, 2006) and examined root mean square error of approximation (RMSEA) and comparative fit index (CFI). Second, we used the Satorra–Bentler log-likelihood difference chi-square test to compare a model with the path from the interaction term to the outcome to the model without the path, as one is mathematically nested within the other. Third, when model fit was improved and an individual interaction term was significant, we examined the direction of effects by splitting the sample at the mean of the moderating variable and examining the effects of BM externalizing problems on infant attention to frustration within the resulting subsamples. We used the mean-split approach rather than splitting the sample 1 *SD* above and below the mean due to the small sample sizes that resulted in the latter approach. Nonetheless, we ran preliminary follow-up analyses splitting the sample at 1 *SD* above and below the mean and at 0.5 *SD* above and below the mean to examine comparability of the results using the different approaches.

The same set of interactions was also tested using the reduced BF subsample. We could not use a latent BF externalizing problem variable in the SEM due to the smaller sample size and relatively low association between two of the three ATOD use variables. Thus, there was no advantage to testing the hypotheses in this subsample using SEM. Instead, we used linear regression analyses in SPSS. We examined a BF externalizing problem factor score (listwise $n = 99$), AM affective state, and the interaction between these two variables as predictors of infant attention during the frustration trials. A parallel regression model in which BF externalizing problems interacted with AF affective state was considered separately.

Results

We first examined the means, standard deviations, and bivariate correlations among study variables. Next, we performed SEM to test the hypothesis that BM characteristics would interact with adoptive parent affective state to predict infant heightened attention during the frustration task. As a subsidiary analysis, we examined this hypothesis using a regression approach with the BF data. Finally, we explored prenatal substance use effects as a potential mediating pathway.

Descriptive Statistics and Correlations

The analytic sample consisted of 348 linked triads for whom data were available on at least two of the three members of the triad. Means, standard deviations, correlations among study variables, and *n* sizes for each variable are summarized in Table 1. Infant attention during the frustration trials was moderately associated with infant attention during the neutral trials ($r = .33$, $p < .001$). The correlation matrix also indicated significant associations among the three BM externalizing measures, significant associations between two of the three BF externalizing measures, and significant associations among about half of the BM–BF externalizing behavior cross correlations. In addition, there were several modest but significant correlations among the remaining variables. For example, BM prenatal ATOD use was correlated with the BM externalizing measures and with two of the BF externalizing measures. BM delinquency was also modestly associated with attention during the frustration trials ($r = .13$, $p < .05$) and was inversely associated with AF affective state ($r = -.12$, $p < .05$), and AM affective state was associated with openness ($r = .12$, $p < .05$). Otherwise, the study variables were no more associated than would be expected by chance.

Evaluation of BM × Adoptive Parent Effects

The SEM analyses used full information maximum likelihood, which has been shown to provide unbiased estimates when data are missing at random (Arbuckle, 1996) and to offer greater statistical efficiency compared to mean-imputation, listwise, and pairwise deletion methods (Wothke, 2000). The first series of models tested infant attention during the frustration trials regressed on the latent BM externalizing behavior variable (ATOD dependence, delinquency, and novelty seeking), AM affective state, and their interaction; AF affective state, adoption openness, infant attention during neutral trials, and infant sex were statistically controlled.

The first of these models (prior to entry of the interaction term) showed an acceptable fit to the data. Higher levels of AM anxious and depressive symptoms were modestly associated with higher levels of infant attention during the frustration trials ($p < .05$). Higher levels of BM externalizing behavior indicated a trend toward being significantly associated with higher levels of infant attention during the frustration trials ($p < .10$). Other than infant attention during the neutral trials ($p < .001$), none of the control variables was associated with infant attention to frustration in this model. Next, a model in which the interaction between BM externalizing problems and AM affective state was fitted to the data. The results are summarized in Figure 1. Compared to the first model, in which this path was fixed at zero, this model fit the data significantly better, Satorra–Bentler χ^2 difference ($df = 1$) = 6.67, $p < .05$. More importantly, the interaction term also was significant ($p < .05$). The AM affective state remained significant ($\beta = .10$, $p < .05$), and the BM externalizing behavior path became significant in the interaction model ($\beta = .17$, $p < .05$).

Decomposition of Interaction Between BM Externalizing Behavior and AM Affective State

To examine the nature of this interaction, the model was run within the subsamples that were above and below the mean on the AM affective state variable; nonsignificant covariates (AF affective state, infant sex, and adoption openness) were omitted given the reduced subsample sizes. In the subsample above the mean on the AM affective state variable ($n = 184$), the model provided a good fit to the data, $\chi^2 = 5.17$, $df = 6$, $p = .523$; CFI = 1.00; RMSEA = .00. The path from BM externalizing problems to the infant attention to frustration was significant ($\beta = .35$, $p < .01$). This model was then rerun with the subsample below the mean on the AM affective state variable ($n = 164$). This model also fit the data well, $\chi^2 = 6.45$, $df = 6$, $p = .38$; CFI = .99; RMSEA = .02. The path from BM externalizing problems to infant attention was not significant ($\beta = -.01$).

The interaction decomposition models were rerun to examine whether the pattern of effects remained when the sample was split at 1 *SD* above and below the mean and at 0.5 *SD* above and below the mean on the AM affective state variable. Due to the reduced sample sizes, these models were considered preliminary. The standardized path coefficients from BM externalizing to infant attention to frustration were in the same direction as the mean-split analyses for both models: .34 at 1 *SD* above the mean of AM affective state ($n = 62$); .36 at 0.5 *SD* above the mean ($n = 121$, $p < .05$); −.04 at 1 *SD* below the mean ($n = 68$); and −.02 at 0.5 *SD* below the mean ($n = 121$). These follow-up analyses support the effects found with the mean-split approach. Infant attention to frustration was regressed on BM externalizing problem factor scores for the two mean-split groups (Figure 2), reflecting the linear regression results using observed (vs. latent) variables and listwise deletion of cases with missing data.

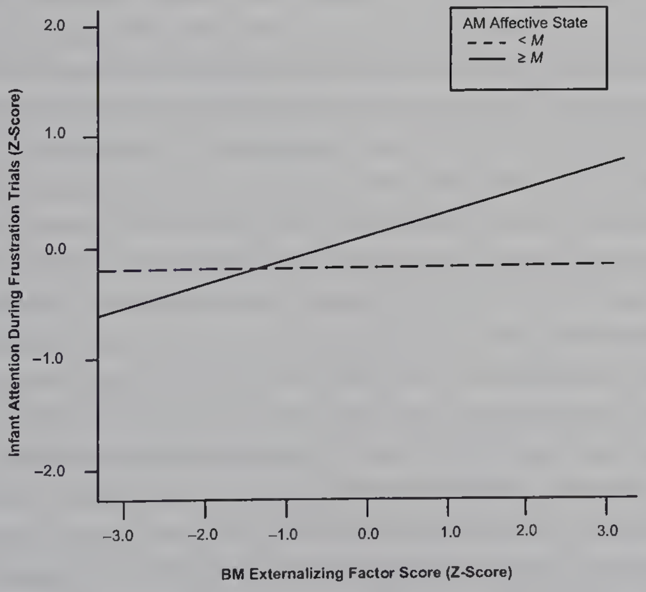

Figure 2. Relations between birth mother (BM) externalizing problems and infants' attention to frustration above and below the mean on the measure of adoptive mother (AM) affective state.

Finally, we ran a similar series of models to evaluate whether AF affective state interacted with BM externalizing to predict infant attention during the frustration task. In these models, AM affective state and the other covariates (described earlier) were controlled. All main effect and interaction paths were nonsignificant, suggesting that the effects described earlier are specific to AM affective state.

Linear Regression: Evaluation of BF × Adoptive Parent Effects

The G × E hypotheses were examined in a parallel way with BF data using linear regression techniques due to the nonconvergence of the latent factor and the smaller sample size. Externalizing behavior problems were represented by the factor score composed of BF ATOD dependence, delinquency, and novelty seeking indicators. Infant attention during the frustration trials was not predicted by this BF composite alone or in interaction with the AM affective state variable, $F(3, 81) = .587$, *ns*, or the AF affective state variable, $F(3, 78) = .255$, *ns*.

Exploratory Models Controlling for BM Prenatal ATOD Use

Next, exploratory models were run to test whether the effect of the interaction between BM externalizing problems and AM affective state on infants' attention during the frustration trials was better accounted for by BM prenatal ATOD use. In general, all models and path coefficients were regarded with caution in these analyses due to the functional relation between general and prenatal ATOD use (i.e., mothers who report never using will also report never using during pregnancy, and mothers who use during pregnancy typically use outside of pregnancy).

Birth mother prenatal ATOD use was entered in the full model as a mediator of interaction effects. That is, BM prenatal ATOD use was regressed on BM externalizing problems, AM affective state, and their interaction, and infant attention to frustration was regressed on BM prenatal ATOD use, attention during neutral trials, infant sex, AF affective state, and adoption openness but not directly on terms involved in the interaction. BM externalizing was significantly associated with BM prenatal ATOD use, but the interaction term was not significant. Additionally, BM prenatal ATOD use did not significantly predict infant attention to frustration. This model was compared with a model that allowed direct predictive paths from BM externalizing, AM affective state, and their interaction to infant attention during the frustration trials. The latter model fit the data better, Satorra–Bentler χ^2 difference ($df = 3$) = 15.46, $p < .05$, and the path from the interaction term to the infant attention outcomes was significant ($p < .01$). Similarly, within the subsample that was above the mean on AM affective state, the reduced model (i.e., exclusion of infant sex, AF affective state, and openness in adoption) provided a marginal fit to the data, $\chi^2 = 14.924$, $df = 9$, $p = .093$; CFI = .960; RMSEA = .060. BM externalizing problems predicted BM prenatal ATOD use ($\beta = .72$, $p < .001$) and infant attention during the frustration trials ($\beta = .48$, $p < .05$), whereas BM prenatal ATOD use did not predict infant attention during the frustration trials ($\beta = -.19$, $p = ns$). The model that fixed the direct path from BM externalizing problems to infant attention during the frustration trials did not fit the data adequately, $\chi^2 = 25.381$, $df = 10$, $p = .005$; CFI = .896; RMSEA = .091. Therefore, the findings did not support BM prenatal ATOD use as an explanation for the G × E findings described above.

Discussion

Recently, researchers from developmental psychology and behavioral genetic perspectives have called for and highlighted the potential value of integrating behavioral genetic and developmental research to improve outcomes for youth and families (Reiss & Leve, 2007; Rutter, 2005). In the current study, we made a preliminary effort to leverage the unique opportunity provided by an adoption design to understand how a specific family environmental experience—infant exposure to adoptive parent anxious and depressive symptoms—might moderate a genetic propensity for externalizing behavior very early in development and, as such, increase the understanding of causal mechanisms during early childhood.

The results suggest that infants are more likely to show heightened attention during a frustration task when they are exposed to an early rearing environment involving elevated maternal anxious and depressive symptoms. Although the direct association between maternal anxious and depressive symptoms and infant attention to frustration was modest in this study, this main effect finding is consistent with prior findings that demonstrate the significant effects of maternal depression in early childhood on young children's problem behaviors (Downey & Coyne, 1990). However, it is unique in that the parents and children were genetically unrelated in the present study, thereby suggesting a pure environmental mechanism of transmission that is unclouded by genetic factors. Beyond the direct effects of AM affective state, the SEM results suggest that maternal affective state moderates the effects of genetic risk for externalizing behavior. That is, the direct effect of birth parent externalizing behavior on infant attention to frustration was amplified in the context of elevated levels of AMs' anxious and depressive symptoms. Researchers have examined the moderating role of *genetic* risk for psychopathology (e.g., birth parent psychopathology; Riggins-Caspers, Cadoret, Knutson, & Langbehn, 2001), but, to our knowledge, this study is the first attempt to examine the affective state of rearing parents on moderating genetic influences in young children. As is shown in Figure 2, genetic risk for externalizing behavior was unrelated to infant attention when AMs were below the mean on anxious and depressive symptoms. Conversely, when AMs were above the mean, genetic risk was exacerbated, with the association between BM externalizing behavior and infant attention during a frustration task becoming significant ($\beta = .35$, $p < .01$).

The specific phenotype measured in the present study was infants' attention, interest, and persistence to a frustrating task. As such, this behavior was considered to reflect an inability to direct attention away from a stressful situation (rather than reflecting more general attention processes). The follow-up analyses examining whether the same G × E processes operated on infant attention during the neutral trials yielded nonsignificant results, suggesting the specificity of maternal affect in moderating effects to situations where the infant might feel frustrated and lack autonomy. Through a combination of genetic liability and emotionally unavailable and dysregulated maternal caregivers, these infants might begin to react with increased attention and intensity under conditions of frustration, perhaps in an effort to solicit caregiver attention or involvement from an anxious or depressed mother. Such reactions during infancy might be the forbearers of noncompliance and reactivity during toddlerhood, when children are in similarly frustrating situations and are subjected to constraints placed upon them by their caregivers (e.g., when a parent asks a child to clean up his or her toys). The reactions of some children can increase under such conditions, escalating into coercive cycles with the parent during childhood (Shaw et al., 1994; Shaw et al., 1998) and evolving into delinquency and antisocial behavior that continues into adolescence (Patterson, Reid, & Dishion, 1992).

Parental Sex Differences

Although support was found for direct and moderating effects of AM affective state on infant attention during a frustration task, the AF results did not support the hypotheses. Similarly, the G × E interaction was not significant when the BF data were modeled. Together, these nonsignificant results for fathers suggest a pattern of maternal linkages to externalizing behavior in young children, in terms of both the rearing environment and genetic influences. The lack of significant findings for the unique contributions of AF affective state was not surprising; prior work has found stronger associations between maternal affective state and child adjustment than between paternal affective state and child adjustment (Meadows et al., 2007). Measuring the respective caregiving roles of both parents in future studies would help elucidate the extent to which this rearing parent environmental effect results from differential levels of caregiving between mothers and fathers or whether there is something unique about maternal affective state irrespective of the level of her caregiving. Alternatively, given that the parenting factors used in the present study have been validated primarily with samples of mothers, other aspects of paternal caregiving in early or later development (e.g., facilitating problem solving in middle childhood) might play a more important role in the development of child problem behavior.

The lack of significant BF effects was unexpected and suggests the possibility of sex-linked transmission of genetic risk for externalizing behavior. Although this is the largest BF sample in a single prospective adoption design collected to date, we could not test models that aggregate genetic risk by forming a composite between BM and BF data because of the large number of nonparticipating BFs and the lack of convergence of indicators for the participating BFs. Further, the results from the BF regression analyses indicate that the direction of effects does not resemble that of BMs, suggesting that a larger sample would not alter the pattern of findings. Sex differences in the heritability of externalizing behavior have been examined in a number of studies. Although some researchers have reported similar patterns of heritability across the sexes (Rhee & Waldman, 2002), others have found that genetic influences are significantly higher in females than in males. For example, Tuvblad, Grann, and Lichtenstein (2006) found heritability estimates of 6% for adolescent boys' antisocial behavior and 59% for adolescent girls' antisocial behavior.

A polygenetic multiple threshold model can be used as a framework to consider the sex differences found in this study (Rhee & Waldman, 2002). In such a model, the sex less afflicted with a behavior might require a greater liability to express that behavior. In the case of externalizing behaviors, females are the less affected sex; thus, the relatives of affected females might be at greater risk of developing externalizing problems than relatives of affected males. In the present analyses, the associations between BM externalizing behavior (compared to BF externalizing behavior) and infant attention during a frustration task were more pronounced, thereby permitting sufficient variation to allow for the detection of environmental moderation of this genetic effect. In addition, as is shown in Table 1, the mean levels of externalizing behavior were only modestly lower for BMs than for BFs, an atypical finding for adult samples that provides some corroborating evidence for the polygenetic multiple threshold model. Parallel evidence in support of polygenetic multiple threshold processes comes from clinical research involving a gender paradox in the severity of disorders. For disorders with an unequal sex ratio, individuals with the lower prevalence rates tend to be more seriously affected and to have more co-occurring diagnoses (Loeber & Keenan, 1994). For example, the likelihood of girls with attention deficit disorder to develop conduct disorder is 40 times greater than for girls without attention deficit disorder, compared to a factor of 14.7 for boys (Szatmari, Boyle, & Offord, 1989). Although the lack of significant effects for the BF analyses should be interpreted with caution because they were counter to study predictions, the two lines of research described above suggest that future research should consider sex-linked explanations when examining G × E interaction processes on externalizing behaviors in early childhood.

Future Directions: Implications for the Development of Preventive Interventions

In conducting this study, we had an implicit goal of exploring possibilities for the development of future preventive interventions by capitalizing on the EGDS adoption study design, which provides information about the processes whereby early environmental experiences can offset or exacerbate genetic strengths and liabilities. As has been noted by others, adoption is an effective intervention, particularly for children living in suboptimal environments who are placed in more enriched environments within the first few months of life (Rutter, O'Connor, & English and Romanian Adoptees Study Team, 2004; van IJzendoorn & Juffer, 2006). Children adopted at an early age typically fare better than their nonadopted counterparts on a range of cognitive and social outcomes. However, in addition to mean level shifts in behavior resulting from adoption, the full adoption design permits the examination of the mechanisms whereby differing early environmental experiences can lead to healthy or less optimal adjustment. In the present study, AM anxious and depressive symptoms moderated the effect of genetic risk for early externalizing problems. If this effect were to be replicated and extended in future research, preventive interventions targeting mothers with affective problems might improve the mental health of the caregiver, in turn alleviating exposure to adverse environmental conditions that might offset the expression of children's genetic risk for externalizing behavior. Although this possibility cannot be directly addressed in the present study until the link between infant frustration and later externalizing problems is confirmed, it is tentatively proposed as a hypothesis for further investigation. Notwithstanding this caveat, the results from two recent intervention trials have provided the first evidence that interventions aimed at reducing parental depression might significantly reduce child behavior problems (Shaw, Dishion, Connell, Wilson, & Gardner, 2009; Weissman et al., 2006), thereby supporting this hypothesis.

Alternative Explanations

Although the results of the present analyses are unique and appear to be robust, several alternative explanations for AM environmental moderation of genetic effects could be possible. First, intrauterine exposure to toxins might mask or confound genetic effects. Although BM prenatal ATOD use does not appear to be a causal mechanism in the associations found here, additional prenatal experiences (e.g., exposure to environmental toxins) have not been examined; thus, other prenatal factors could be associated with the pattern of findings described here.

Second, trends in adoption practices such as selective placement (agency matching of birth and adoptive parent characteristics) and openness (contact and knowledge between birth and adoptive families) can pose a threat to the assumptions underlying the adoption design and bias model estimates. For example, an adopted child might be more likely to resemble his or her birth parents (artificially inflating genetic estimates) if the birth parents are in direct contact with the child or if the birth parents have actively selected an adoptive home that closely mirrors their own environment. As such, an openness construct was included in the analytical models; this construct neither yielded a significant association with the dependent measure nor accounted for significant variance in the relation between BM externalizing behavior, AM affective state, and infant attention during a frustration task (Figure 1). Ruling out the possible effects of selective placement is more complex because the associations between a birth parent characteristic and an adoptive parent characteristic could indicate selective placement or could indicate genetically influenced evocative behaviors in the child that have modified adoptive parent behavior to be more similar to birth parent characteristics. Previously, we correlated a set of birth parent characteristics with a set of adoptive family characteristics that were *unlikely* to be influenced by evocative effects (i.e., demographic characteristics) to consider the possible effects of selective placement (Leve et al., 2007). No relation was significant. Thus, systematic selective placement was not identified, although it cannot be fully ruled out as a possible explanation for the present effects.

Third, the G × E effects found in the present study could have resulted from evocative genotype–environment correlation (*r*GE), which has been found in other samples of infants and toddlers (Forget-Dubois et al., 2006). In the present study, evocative *r*GE would have been noted if the genetically influenced externalizing behavior of the infant directly influenced AM anxious and depressive symptoms and confounded the G × E effects. Although longitudinal designs are needed to truly separate the directionality of evocative effects, the correlation between AM affective state and BM externalizing behavior in this study was nonsignificant. Similarly, the correlations between fathers (adoptive and birth) were nonsignificant (Table 1). These results suggest that *r*GE is likely not confounding the moderating effects shown by AM affective state.

Fourth, in the present study, we examined a single outcome. Based on the research reviewed earlier, we hypothesized that attention, interest, and persistence toward a frustrating situation would reflect an underlying genetic predisposition toward later externalizing behavior, with children at genetic risk showing heightened attention when frustrating constraints were placed upon them. Alternatively, the barrier frustration task might simply elicit vulnerabilities to negative affectivity rather than differences in attention processes. To test this alternative hypothesis, we examined the final models using negative affect during the barrier task as the outcome using the same coding system as the attention variable. No significant G × E effects were found. Further, there were significantly stronger associations between negative affect and attention in the control trials ($r = -.53$, $p < .001$) than in the frustration trials ($r = -.15$, $p < .05$), suggesting the relative independence of attention and negative affect within the context of a frustrating situation.

Fifth, based on prior findings in the literature, we hypothesized that the primary genetic risk factor associated with infant attention would be externalizing problems and that the primary early environmental risk factor would be adoptive parent anxious and depressive symptoms. However, given the modest amount of variance accounted for in our results, it is plausible that additional genetic influences and family environmental contexts affect infant attention to frustration. Although rates of adoptive parent externalizing behavior were low in this sample, we tested whether similar main effects and interaction effects would be found when adoptive parent antisocial behavior or novelty seeking was entered as the environmental measure (using identical measures as were used for birth parents). In this post hoc set of analyses, no main effects or interaction effects were found, providing converging evidence for maternal affective state as a central environmental variable from birth to 9 months. We next examined alternative genetic risk factors and conducted a post hoc analysis of whether BM anxiety and depression (using identical measures as were used for adoptive parents) would show associations with infant attention during a frustration task. Although there was no main effect, the interaction between BM affective state and AM affective state was significant, suggesting a potential explanatory role of BM affective state. However, given the relatively high association between BM externalizing problems and BM affective state in this sample ($r = .40$, $p < .001$) and the fact that the original interaction between BM externalizing problems and AM affective state remained significant while controlling for BM affective state, the effects of BM affective state do not appear to be as strong as the effects of BM externalizing problems in this study. Further, the findings from prior research on attention to frustration have suggested associations with later externalizing problems (rather than internalizing problems), suggesting that our reliance on prior research to guide the selection of genetic and environmental risk variables in the present study was appropriate.

Limitations

To our knowledge, the present study is the first to examine how early exposure to maternal anxious and depressive symptom moderates genetic influences on risk for later externalizing behavior. The use of a prospective adoption design enabled us to make associations between the phenotypic behavior of the birth parent and the phenotypic behavior of an infant to examine underlying inherited predispositions toward externalizing behavior. However, the present study is not without limitations. First, because cross-sectional data were used, longitudinal pathways could not be tested. The longitudinal nature of the study will enable us to examine, in subsequent years, how the moderating effects of AM affective state unfold over time. Of relevance to informing preventive intervention, it will be critical to examine whether the mechanisms affecting infant attention are in fact found to lead the child toward a trajectory of early and persistent externalizing problems. Without such longitudinal data, we can only speculate about the intermediary phenotypic pathways to externalizing behavior and cannot make conclusive interpretations. Further, the moderating effects of the early home environment were already present at 9 months of age; studies beginning earlier in development are needed to help define the causal mechanisms whereby early exposure to maternal anxiety and depression result in the expression of risk in the child.

In addition, although findings from prior research on attention to frustration have suggested associations with later externalizing problems, it is likely that additional genetic influences and family environmental contexts affect infant attention to frustration. Specifically, attachment is a key environmental influence on later infant externalizing behavior (Smeekens et al., 2007), and cognitive functioning is known to be a heritable characteristic related to externalizing behavior (DeYoung et al., 2006). Such variables (not assessed at our 9-month assessment) might be associated with the infant attention to frustration variable. Additional research is needed to test these alternate environmental and genetic pathways.

Finally, although our sample was representative of birth and adoptive families from the agencies participating in this study, the adoptive families had high educational and economic backgrounds and low rates of externalizing problems compared to national norms. Thus, the discrepancy in sociodemographic characteristics often found between birth and adoptive parents was replicated in the present study, indicating the potential restriction of range in the environment that has been noted in prior reviews of the adoption design (Stoolmiller, 1999). However, in a recent systematic test of range restriction biases, McGue et al. (2007) found negligible effects on estimates of heritability and the environment, even when range restriction was present. Further, the adoptive parents in our study had an adequate range of depression and anxiety symptoms (Leve et al., 2007). Other researchers have found that genetic influences on externalizing behavior are more important in families with more advantaged environments, whereas the shared environment is more important in more economically disadvantaged environments (Tuvblad et al., 2006). Thus, the generalizability of findings to high-risk home environments and more ethnically diverse samples needs to be documented before stronger conclusions can be drawn.

Building a New Biodevelopmental Framework to Guide the Future of Early Childhood Policy

Jack P. Shonkoff
Harvard University

Four decades of early childhood policy and program development indicate that evidence-based interventions can improve life outcomes, and dramatic advances in the biological and behavioral sciences now provide an opportunity to augment those impacts. The challenge of reducing the gap between what we know and what we do to promote the healthy development of young children is to view current best practices as a starting point and to leverage scientific concepts to inspire fresh thinking. This article offers an integrated, biodevelopmental framework to promote greater understanding of the antecedents and causal pathways that lead to disparities in health, learning, and behavior in order to inform the development of enhanced theories of change to drive innovation in policies and programs.

Dramatic advances in neuroscience, molecular biology, genomics, and the behavioral and social sciences are deepening our understanding of how healthy development happens, how it can be derailed, and what societies can do to keep it on track. We now know that genes provide the initial blueprint for building brain architecture, environmental influences affect how the neural circuitry actually gets wired, and reciprocal interactions among genetic predispositions and early experiences affect the extent to which the foundations of learning, behavior, and both physical and mental health will be strong or weak (Fox, Levitt, & Nelson, 2010; Meaney, 2010). A strong foundation lays the groundwork for responsible citizenship, economic prosperity, healthy communities, and successful parenting of the next generation. A weak foundation can seriously undermine the social and economic vitality of a nation (Knudsen, Heckman, Cameron, & Shonkoff, 2006).

Decades of research in child development have taught us that families and communities play the central role and bear most of the costs of providing the supportive relationships and positive learning experiences that young children need for healthy development (Shonkoff & Phillips, 2000). There also has been considerable documentation of the extent to which public policies and formal services can enhance developmental outcomes for young children living in a wide variety of circumstances (Karoly, Kilburn, & Cannon, 2005). Building on this extensive knowledge base, striking new discoveries in the biological sciences are presenting policy makers and civic leaders with provocative insights into the far-reaching influences of early developmental processes that were not appreciated as recently as a decade ago. The extent to which advances in molecular biology are already beginning to transform the way we diagnose and treat disease illustrates one example of this new world. The challenge before us is to capitalize on the capacity of this scientific revolution to stimulate creative new ways of thinking about how to address a much broader range of societal concerns, including education reform, workforce development, health promotion, prevention of disease and disability, protection of children from the consequences of maltreatment and exploitation, reduction in violent crime, and alleviation of poverty.

Developmental Frameworks and Theories of Change

Current Models

Early childhood policies and practices over the past several decades have been guided by several theoretical models of human development that have been refined over time. These include the transactional model formulated by Sameroff and Chandler (1975) and later adapted to the challenges of early childhood intervention by Sameroff and Fiese (1990, 2000), the ecological model articulated by Bronfenbrenner (1979), and the concepts of vulnerability and resilience developed by Werner and Smith (1982), Garmezy and Rutter (1983), and Rutter (2000). Together these models underscore the extent to which life outcomes are influenced by a dynamic interplay among the cumulative burden of risk factors and the buffering effects of protective factors that can be identified within the individual, family, community, and broader socioeconomic and cultural contexts. Each of these models also emphasizes the influence of reciprocal child–adult interactions in the developmental process, thereby underscoring the importance of stable and nurturing relationships, as well as the recognition that young children play an active role in their own development. The challenges of applying these multidimensional models, however, lie in their complexity. That is to say, the acknowledgment of numerous, interactive influences on developmental outcomes underscores both the futility of searching for simple solutions to complicated problems and the difficulty in choosing which variables to include and which to omit when one is designing a specific policy, program, or research project.

Building on these broadly supported models of child development, the field of early intervention for children living in disadvantaged circumstances (most typically associated with poverty) in the United States is currently driven by a theory of change that emphasizes the provision of enriched learning opportunities for the children and a combination of parenting education and support services for their families (usually focused exclusively on mothers), in community-based centers and/or the home. Over four decades of program development and evaluation, this basic model has been implemented successfully in a number of flagship demonstration projects, each of which has produced desirable impacts on a range of long-term outcomes, including increased rates of high school graduation and adult earnings, as well as reductions in special education referrals, welfare dependence, and incarceration, among others (Heckman, 2006; Shonkoff & Phillips, 2000).

Building an Enhanced Framework to Inform Innovative Policy

Although the basic principles of development described above have stood up well over time, advances in the biological and social sciences now offer an opportunity to formulate an augmented framework to drive a new generation of early childhood policies and practices. Support for this new framework is underscored by a rich and rapidly growing evidence base that illustrates the extent to which early experiences are biologically embedded in the development of multiple organ systems, with long-term impacts on metabolic regulation and cardiovascular health as well as the mastery of cognitive, language, and social skills (Hertzman, 2000; Meaney, 2010; Shonkoff, Boyce, & McEwen, 2009). Beyond its potential benefits for policies that affect all young children, the proposed biodevelopmental framework alerts decision makers to the particular importance of addressing the needs of those who are the most disadvantaged at the earliest ages. Equally important, yet potentially more challenging from a policy planning and implementation perspective, new research into individual differences in biological sensitivity to context offers significant promise in helping to explain why some children appear to do well in the face of adversity and why selected interventions appear to be effective for some children and not for others (Obradovic, Bush, Stamperdahl, Adler, & Boyce, 2010; O'Neal et al., 2010).

This new framework for research and policy is informed by a growing body of evidence that the foundations of healthy development and the origins of many impairments can be found among biological "memories" that are created through gene–environment interactions in the early years of life, in some cases beginning as early as the prenatal period (e.g., Barker, 1997; Davis & Sandman, 2010; D'Onofrio et al., 2010). These patterns, often mediated through epigenetic modifications, can be manifested within the circuitry of the developing brain and the physiological systems that influence a variety of biological functions such as stress management, immunological responsiveness, metabolic and neuroendocrine regulation, and cardiovascular integrity. The scientific concepts that explain these phenomena are derived from evolutionary biology, grounded in the assumption that the immature organism "reads" salient environmental characteristics in the service of developing the capacity to adapt to the environment in which it "expects" it will live. When early experiences are nurturing, contingent, stable, and predictable, healthy brain development is promoted, and other organ regulatory systems are facilitated. When early experiences are fraught with threat, uncertainty, neglect, or abuse, stress management systems are overactivated, and the consequences can include disruptions of developing brain circuitry as well as the establishment of a short fuse for subsequent activation of the stress response that leads to greater vulnerability to a host of chronic diseases. Although more research is needed to elucidate the precise nature and full range of causal mechanisms that mediate these effects, there is compelling evidence from recent studies of young children who have been abused or subjected to chronic neglect in institutionalized settings to support the conclusion that significant adversity early in life can induce physiological responses in the service of short-term survival benefits that come at considerable cost to long-term adaptive capacities as well as both physical and mental health (Cicchetti, Rogosch, Gunnar, & Toth, 2010; Pollak et al., 2010). The relation between low birth weight associated with severe nutritional deficiencies in utero and greater risk of subsequent metabolic syndrome, central body fat distribution, obesity, hypertension, insulin resistance, and cardiovascular disease is another example of this phenomenon (Barker, Osmond, Forsen, Kajantie, & Erikson, 2005).

In an effort to educate policy makers about the biology of adversity and its consequences for both health and development, the National Scientific Council on the Developing Child (2005) proposed a conceptually guided taxonomy based on three categories of stress experience—positive, tolerable, and toxic—to differentiate normative life challenges that are growth promoting from significant threats to long-term health and development that warrant intervention. It is important to note that these three categories refer to the physiological expression of the stress response and not to the specific stressors themselves. Although the underlying biology of these distinctions awaits empirical validation, their conceptual basis is grounded in well-established scientific principles.

Positive stress is characterized by moderate, short-lived increases in heart rate, blood pressure, serum glucose, and circulating levels of stress hormones such as cortisol and inflammatory cytokines such as interleukin-6. Precipitants include the challenges of dealing with frustration, adjusting to a new child-care setting, and other normative experiences. The essential characteristic of positive stress is that it is an important aspect of healthy development that is experienced in the context of stable and supportive relationships that facilitate adaptive responses that restore the stress response system to baseline.

Tolerable stress refers to a physiological state that could potentially disrupt brain architecture (e.g., through cortisol-induced damage of neural circuits in the hippocampus) but is buffered by supportive relationships that facilitate adaptive coping. Precipitants include the death or serious illness of a family member, parental divorce, homelessness, a natural disaster, or community violence. The defining characteristic of tolerable stress is the support provided by invested adults that helps restore the body's stress-response systems to baseline, thereby preventing neuronal disruptions that could lead to long-term consequences such as posttraumatic stress disorder.

Toxic stress refers to strong, frequent, and/or prolonged activation of the body's stress-response systems in the absence of the buffering protection of stable adult support. Major risk factors include extreme poverty, recurrent physical and/or emotional abuse, chronic neglect, severe maternal depression, parental substance abuse, and family violence. The defining characteristic of toxic stress is that it disrupts brain architecture, adversely affects other organs, and leads to stress management systems that establish relatively lower thresholds for responsiveness that persist throughout life, thereby increasing the risk of stress-related disease or disorder as well as cognitive impairment well into the adult years.

The basic elements of the biodevelopmental framework presented in this article are organized within three sets of target domains: (a) interactions among foundations of healthy development and sources of early adversity, (b) measures of physiological adaptation and disruption, and (c) both positive and negative outcomes in learning, behavior, and health. These domains provide a scaffold for the design of further research into basic developmental processes as well as a roadmap for a new era in early childhood policy focused on specific foundations of health and sources of adversity that offer promising targets for innovative intervention strategies, beginning as early as the prenatal period.

The first target area—the environment of relationships in which a young child develops—requires attention to a continuum from nurturing, responsive caregiving to neglectful or abusive interactions. This includes both family and nonfamily members as important sources of stable and growth-promoting relationships as well as critical buffers against significant threats to healthy development. The second target area—the physical, chemical, and built environments in which the child and family live—requires protection from neurotoxic exposures such as lead, mercury, and organophosphate insecticides; safeguards against injury such as the use of infant seat restraints in automobiles; and availability of safe neighborhoods and the associated social capital that supports families with young children. The third target area for intervention—appropriate versus poor nutrition—requires attention to the availability and affordability of nutritious food; parent knowledge about age-appropriate meal planning for young children that assures adequate intake of both macronutrients (e.g., protein, carbohydrates, and fat) and micronutrients (e.g., vitamins and minerals); and effective controls against the growing problem of excess caloric consumption and early obesity.

The second set of domains in the proposed framework includes a variety of physiological responses that present promising opportunities for a new generation of mediating, biological variables whose measurement might inform the effects of a broad range of experiences and interventions. In some cases, these physiological markers may be associated with specific adverse events or experiences that occur during sensitive periods in the development of the brain or other organ systems. The lifelong cognitive deficits and physical impairments associated with first trimester rubella infection or significant prenatal alcohol exposure are two prominent examples of this type of time-sensitive effect. In other circumstances, physiological changes may reflect the cumulative damage or biological "wear and tear" caused by risk factors such as recurrent abuse or chronic neglect that build up over an extended period of time. When early influences have been positive, physiological systems are typically healthy and adaptive. When influences have been adverse, systems may be dysfunctional and lead to impaired learning, maladaptive behavior, illness, disability, and a shortened life span. In both cases, genetic predisposition moderates the effects of environmental influence and differential sensitivity to context can result in differential outcomes (Obradovic et al., 2010). The identification and measurement of these physiological "footprints" offers considerable promise as a potential source of short- and medium-term markers of both resilience and vulnerability in the face of adversity, as well as potential metrics for assessing the impact of early life interventions on mediators of longer term outcomes (such as chronic diseases) that require decades to confirm. Potentially promising biomarkers that appear to be worthy of careful study include measures of oxidative stress, inflammatory cytokines, telomere length, telomerase levels, and epigenetic profiles, among many others.

The third set of target domains includes adult outcomes in educational achievement and economic productivity (high vs. low), health-related behaviors that are enhancing (e.g., nutritious diets, frequent exercise, and use of condoms to prevent sexually transmitted disease) versus those that are threatening (e.g., smoking, alcohol abuse, illicit substance use, unprotected sexual activity, antisocial behavior, and violent crime), and health status (well-being vs. disease or disorder). Although greater details regarding precise causal sequences remain to be elucidated, increasing evidence supports the conclusion that many aspects of these domains of adult competence and health can be influenced by early life experiences that are amenable to intervention.

The Evolving Context of Early Childhood Policy in the United States

The origins of public support for the notion of intervening in the lives of disadvantaged young children were fueled by four foundational influences in the 1960s—President John Kennedy's interest in mental retardation, President Lyndon Johnson's determination to eliminate the intergenerational cycle of poverty, the moral force of the civil rights movement, and emerging scholarship that challenged the prevailing view of genetic determinism and promulgated the novel idea that intelligence could be influenced by experience (Bloom, 1964; Hunt, 1961). When President Johnson called on policy makers and researchers to design a War on Poverty, they created school breakfast programs, neighborhood health centers, and a preschool summer enrichment project named Head Start, among a host of other initiatives. Over the intervening years, randomized controlled trials have demonstrated that a variety of early childhood interventions (including well-studied programs with extended longitudinal follow-up data such as the Perry Preschool Project, Abecedarian Program, and Nurse Family Partnership) can clearly make a positive difference in the development of disadvantaged young children (Campbell & Ramey, 1994; Olds, 2006; Schweinhart, 2005). After more than 40 years of concurrent advances in the science of early childhood development, the challenge facing policy makers at the end of the first decade of the 21st century is clear—it is time to leverage new scientific knowledge in the service of generating new intervention strategies that will produce substantially greater impacts.

We know more now than ever before about how young children learn and about how to facilitate the development of competencies in a variety of domains. We also have greater insights into how significant adversity can produce disruptive physiological effects on the developing brain, cardiovascular system, and immune system that can have lifelong impacts on both educational achievement and health. As the notion of early childhood policy for children and families is attracting the interest of increasing numbers of public and private sector leaders across the political spectrum, these rapidly moving scientific frontiers offer unprecedented opportunities to stimulate new thinking. With the demand for prudent investment increasing and the pressures on resource allocation growing, three challenges have become increasingly clear.

First, there is marked variability in the quality of implementation of successful programs as they are taken to scale. Demonstration projects tell us what is possible, but their replication on a broader scale has been remarkably uneven. In some cases, failure to achieve comparable impacts has been attributed to the difficulty of reproducing the charismatic leadership and exceptional motivation displayed by those who launch new programs. Others point to the inevitable shortcomings of replication efforts that attempt to serve more children at lower costs by hiring less well-trained staff and burdening them with large caseloads.

Second, increasing evidence indicates that the most effective interventions for children living in poverty produce positive outcomes, but the magnitude of their impacts is typically modest in size. This is perhaps best illustrated in 40-year follow-up data from the most frequently cited early childhood program, the Perry Preschool Project, which reported higher rates of high school graduation (from 45% to 66%) and lower rates of arrest for violent crime (from 48% to 32%) for program participants compared with a randomized control group (Schweinhart, 2005). By any reasonable standard, the magnitude of these intervention impacts would be judged as impressive. However, the fact that one third of the program participants did not graduate high school and another third were arrested indicates the need for more effective intervention strategies. Longitudinal follow-up data on recipients of home visiting services through the Nurse Family Partnership Program support a comparable conclusion (Olds, 2006). Statistically significant impacts on long-term outcomes can be achieved, but effect sizes are often modest and persistent disparities remain to be addressed.

Third, large numbers of young children and families who are at greatest risk, particularly those experiencing toxic stress associated with persistent poverty complicated by child maltreatment, maternal depression, parental substance abuse, and/or interpersonal violence, do not appear to benefit significantly from existing programs. Highly disorganized parents are less likely to seek services and more likely to drop out of programs when they do enroll. When they are successfully engaged, the needs of families facing exceedingly complex social and economic disruptions typically overwhelm conventional early childhood program staff whose expertise is restricted to child development and parenting education. Consequently, the evaluation literature on interventions for children in highly distressed families, such as programs for children who have been victims of abuse or neglect, reveals relatively limited evidence of success (MacMillan et al., 2007).

Together these three challenges underscore the need for a new era in early childhood policy and practice that is guided by science and driven by leadership that combines a strong sense of civic responsibility, an informed understanding of the positive returns that can be generated by wise investment, and a willingness to explore new ideas. Within this context, the field of early childhood intervention currently requires the concurrent pursuit of two separate, yet complementary, paths. One track leads toward closing the gap between what we know and what we do right now. Its course is well marked–enhanced staff development, increased quality improvement, appropriate measures of accountability, and expanded funding to serve more children and families. The second path heads into less well-charted territory, yet its purpose is deeply compelling–to create a new mind-set that promotes innovation, invites experimentation, and leverages the frontiers of both the biological and social sciences into transformational changes in policy and practice. The first path will bring state-of-the-art services to greater numbers of children and families. The second positions current best practices as a promising starting point, not a final destination. Both courses are essential.

Crafting a Science-Based Transition Into a New Era

In 2000, the National Research Council and Institute of Medicine produced a report entitled, ''From Neurons to Neighborhoods: The Science of Early Childhood Development'' which proposed three broad sets of research recommendations: (a) integrating child development research, neuroscience, and molecular genetics; (b) integrating the basic science of human development and the applied science of early childhood intervention; and (c) improving evaluations of early childhood interventions (Shonkoff & Phillips, 2000). Striking scientific advances over the ensuing decade now underscore the compelling need for comparable innovation in policy and practice. The following four objectives are offered as promising directions for such efforts:

The need for an expanded definition of evidence that includes well-established scientific concepts as well as benefit-cost data and the results of randomized controlled studies. The growing demand for evidence-based policies and programs is an increasingly powerful force in the early childhood policy arena. Accountability protects the interests of those who rely on services and those who provide them no less than it meets the needs of those who are responsible for funding them. The question is not whether decisions about the allocation of resources should be informed by evidence, but whether the current definition of evidence that guides early childhood investments may be too narrow. There can be no disagreement with the assertion that randomized experiments remain the gold standard for comparing the efficacy and effectiveness of alternative interventions. The value of cost effectiveness and cost–benefit assessments for calculating the monetary returns achieved from selected interventions is also not in question. That said, although these well-established sources of evidence provide useful information about existing services, they offer relatively little guidance for the compelling task of innovation.

Core concepts of development that meet the rigorous criteria of scientific peer review represent an underutilized yet equally important source of evidence for the policy arena. The extensively documented influence of early experience on gene expression is evidence that poor school performance is not an inevitable consequence of growing up in poverty. The disruptive impact of toxic stress on the development of neural circuitry in the immature brain, and the special sensitivity of the hippocampus that contains much of the neural infrastructure for simple memory and early learning, provide compelling evidence of the need for intensive intervention for very young children who have been abused or neglected. The inextricable interactions among neural circuits that subsume cognitive, language, and emotional capacities provide more than enough evidence to indicate that attention to the mental health of children experiencing significant adversity may be as important to their preparation for school success as exposure to experiences rich in language and literacy. Although evidence documenting the adverse effects of exposure to violence on brain development does not tell us anything about the effectiveness of a specific intervention program, it does underscore the need for dramatic rethinking of marginally effective programs for very young children who live in highly threatening environments. Although quantitative data from cost–benefit studies can help policy makers calculate the financial returns that can be expected from existing services, they offer relatively little guidance for creative agency directors or service providers who are motivated to develop new ideas.

The challenge facing those who seek to reduce the gap between what we know from the biological and behavioral sciences and what we do through policy and practice is to look beyond the program evaluation literature alone and leverage sound scientific concepts to drive innovation. When program evaluation data are presented favorably by advocates and dismissed as methodologically flawed by critics, responsible policy makers can still make informed decisions based on sound scientific principles, followed by ongoing evaluation to determine the impacts of their choices. In short, evidence from randomized experiments and cost–benefit studies is instructive but it simply tells us what we have learned from the past. When these data are augmented by evidence grounded in well-established scientific principles, tempered by a balance of wisdom and creativity, promising new ideas are more likely to emerge.

The need to bring a science-based approach to understanding how early childhood policies and programs can be more responsive to variations in cultural context as well as adversity associated with racial or ethnic discrimination. Acknowledgment of the importance of cultural competence in early childhood policy and practice is common, but scientific investigation of the impact of different childrearing beliefs and practices on early brain development is nonexistent. Moreover, although the need for more behavioral research into the normative development of children who grow up in a variety of cultural contexts is clear, it is essential that such research include more analyses of within-group variability rather than continue to focus primarily on between-group differences. The extent to which advances in the biology of adversity may provide greater insights into the causes of disparities in health and learning outcomes associated with minority group status also awaits further study. Recent findings that children with high neurobiological stress reactivity are more likely to exhibit maladaptive outcomes in the face of significant adversity but better adaptation in the context of low adversity suggests a particularly compelling direction for additional research in this area (Obradovic et al., 2010).

Garcia Coll et al. (1996) proposed an innovative conceptual model for developmental research on minority populations that differed from previous frameworks by placing constructs related to social position and social stratification at the core of their formulation of child development rather than at the periphery. This approach is based on the assumption that stratifications associated with racism, prejudice, discrimination, and segregation have important effects on the development of minority children, particularly with respect to the impacts of segregation, which can be manifested through various combinations of residential, economic, social, and psychological separation or frank isolation. In a related fashion, the cultural distance between professional staff in early childhood programs who are predominantly representative of the dominant culture and the increasingly diverse population of families with young children they are asked to serve presents a clear challenge that has generated considerable rhetoric, yet relatively little productive action. More empirical data on the developmental consequences of minority group status for young children, separate from the influence of social class, would promote a more constructive approach to this issue.

The need to overcome the persistent fragmentation that typifies health, education, and human services systems by leveraging an integrated, science-based framework rather than negotiating interagency agreements among conceptually disconnected programs. The initial rationale for establishing the National Research Council and Institute of Medicine Committee that produced "From Neurons to Neighborhoods" was a firm belief that the fragmented world of early childhood policy, practice, and research was guided by a single underlying science of early childhood development that needed to be articulated. As our understanding of that unified science base has deepened, the persistent disconnection that typifies the multiple policy streams that address early childhood concerns has become increasingly untenable. The contrast between research-driven attempts by departments of education to provide enriched preschool programs for low-income children and resistance by welfare departments to the establishment of high-quality standards for child care for young children whose mothers face mandated employment regulations is one striking example. Another prominent disconnection is the primary focus on physical safety and the absence of expertise in early childhood mental health within child protective services systems that have responsibility for the well-being of young children who have been abused or neglected. In these and many other circumstances, improved outcomes for children facing significant adversity are most likely to be achieved through the coordinated application of a unified, science-based framework across agencies and sectors, not through continuing attempts to foster improved interagency cooperation among disparate systems that are guided by divergent, historical traditions rather than convergent, contemporary knowledge.

The need to formulate and test new theories of change to drive more effective interventions. Early childhood policies and practices are likely to advance best within an open environment that engages a broad diversity of values and expertise, promotes intellectual flexibility and creativity, and encourages a willingness to take risks and learn from failure. This is not meant to minimize the continuing importance of efforts that focus on incremental improvements in the quality of existing programs. It is simply intended to underscore the need for dramatic rethinking in the search for more effective intervention strategies.

The biodevelopmental framework described earlier presents an integrated approach for addressing the early childhood roots of disparities in learning, behavior, and health. Advances in neuroscience suggest two currently underaddressed threats to early development that are particularly promising candidates for greater attention. The first and most compelling is the need for more effective intervention strategies to reduce the adverse biological effects of toxic stress on developing brain circuits and other organ systems. As noted above, although the underlying biology is likely to be exceedingly complex and resistant to simple remedies, there is sufficient evidence right now to support substantial new investments in innovative, relationship-based interventions for young children burdened by the stresses of child maltreatment, significant parental mental health impairments (particularly maternal depression and substance abuse), or family violence. Another candidate domain for increased attention, which is closely associated with the immediate consequences of toxic stress, is the disruptive impact of child mental health problems on early learning. In short, the provision of rich, center-based learning experiences for young children is not sufficient to prevent developmental lags if the children are burdened by anxieties or fears as a result of disruptive life circumstances that are not being addressed directly. Similarly, the provision of information on child development and advice on parenting is not sufficient for mothers and fathers with low income and limited education if the parents themselves are having considerable difficulty coping with the stresses of poverty, depression, substance abuse, food insecurity, homelessness, and/or neighborhood violence.

Stated bluntly, precipitants of toxic stress in the lives of vulnerable children and their families are not currently addressed sufficiently. Although there is a growing evidence base for effective treatment of behavioral and mental health problems in young children, the incorporation of that expertise is extremely limited in the typical early care and education center. The absence of explicit intervention strategies to address the considerable financial burdens experienced by low-income families whose children are enrolled in early childhood programs presents another serious gap, particularly in the face of evidence that the experience of living in poverty between the prenatal period and age 5 appears to have a strong association with subsequent adult earnings and work hours (Duncan, Ziol-Guest, & Kalil, 2010). Finally, the increasing racial and ethnic diversity of the early childhood population and its varied needs demands a deep commitment to the critical task of building, testing, and continually refining more sophisticated and multidimensional theories of change that speak to a broad range of childrearing beliefs and practices.

A Global Perspective on Early Childhood Development

Advances in the natural sciences generate core biological concepts that apply to all animal species. One of the central principles of this growing knowledge base is the critical role of early experiences in shaping the developmental process, whether the subjects of investigation are rodents in laboratory cages, rhesus macaque monkeys in primate research centers, or humans living in a wide variety of social, political, or economic environments. In the wealthiest countries in the world, where economic disparities, racial or ethnic discrimination, and other social challenges are associated with persistent gaps in educational achievement and health status, science can inform the development of innovative policies and practices to mitigate the negative impacts of adversity on young children. In the lowest income countries, which continue to struggle with severe malnutrition, debilitating infection, high child mortality rates, and limited educational achievement, science offers a promising opportunity to augment policies focused exclusively on child survival with a complementary array of investments in early childhood development that will help build the human capital needed to overcome deeply entrenched poverty and promote a broader social and economic agenda.

Over the past decade, the concept of early childhood development has received increasing attention in several high-profile international documents and reports, including the Education for All Dakar Declaration (UNESCO, 2000), the United Nations Millennium Development Goals (United Nations, 2000), the WHO Commission on Social Determinants of Health (Commission on Social Determinants of Health, 2008), and the 2007 *Lancet* series on child development in low-income countries, which estimated that 200 million children worldwide are not reaching their cognitive potential as a consequence of deep poverty (Grantham-McGregor et al., 2007). Concurrent with this growing global awareness, UNICEF (2009) reported that more than 30 governments have established national early childhood policies and 70 have some type of national mechanism to coordinate programs across ministries or sectors.

Despite these positive trends, however, substantial gaps remain to be closed. More than half of the world's governments do not have any policy or coordination mechanism related to early childhood health and development, and those that have articulated policies are typically guided by statements of intent rather than enforceable or implementable plans. In a parallel fashion, although the first goal articulated in the 2000 Dakar Declaration calls for "expanding and improving comprehensive early childhood care and education," it is the only goal without a quantifiable indicator or specific target by which progress can be measured. Finally, few of the major international donors have identified early childhood as a specific component in their funding strategies and most allocate less than 2% of their development assistance for education at the preprimary school level (UNESCO, 2006).

Generally speaking, global understanding of the science of early childhood development and its implications for framing policy priorities remains limited. This is further complicated by the paucity of available data to determine which interventions have measurable impacts on child well-being in a variety of political and cultural contexts. The need for coordination across policy sectors (i.e., involving ministries in health, education, and finance) as well as among the senior leadership within international agencies adds to the current challenges. Consequently, objectives like enhanced early childhood development are very difficult to achieve and sustain as they tend to be departmentalized, with child survival being the focus of the health sector and early child care and education that of the education sector. The proposed biodevelopmental model could be used to support a science-based strategy to transcend those barriers.

Concluding Thoughts

After four decades of scientific advances and early childhood program development, we have solid evidence that underscores the role of positive, early experiences in strengthening brain architecture and a growing understanding of how significant adversity damages brain circuits and undermines lifelong learning, behavior, and both physical and mental health. Moreover, neurobiology tells us that the later we wait to invest in children who are at greatest risk, the more difficult the achievement of optimal outcomes is likely to be, particularly for those who experience the early biological disruptions of toxic stress.

Complementing this knowledge base in the biological and developmental sciences, program evaluation data tell us that we can improve the life trajectories of children who face the burdens of poverty and social disadvantage, but the quality of program implementation and the magnitude of measured impacts are highly variable. This evidence base is supported further by the anecdotal reports of early childhood program staff who indicate that they see the positive impacts of their efforts on a daily basis yet are often overwhelmed by the emotional, behavioral, and social problems of many of the children and families they serve. All available information points to the same conclusion—intervention in the early years can make an important difference, and the magnitude of policy and program impacts must be increased.

Science tells us that the early childhood period is a time of both great opportunity and considerable risk, and its influence can extend over a lifetime. The foundational importance of the early years is increasingly appreciated across the political spectrum, and there is growing recognition that families, communities, the workplace, and government each has a shared interest and distinctive, noninterchangeable role to play in assuring the healthy development of all young children. Stated simply, the science of early childhood and brain development is strong and growing, the moral imperative for preventive action is compelling, and the potential social and economic returns on investment are substantial.

The distinguished biologist E. O. Wilson (1998) wrote, "We are drowning in information, while starving for wisdom. The world henceforth will be run by synthesizers, people able to put together the right information at the right time, think critically about it, and make important choices wisely.'' The challenge for informed policy making is to focus less attention on competing interpretations of program evaluation data that demonstrate statistically significant but relatively modest impacts and to direct more investment toward generating and testing new ideas about how to improve life outcomes more effectively for those whose needs are not being met. The complementary challenge for the research community is to focus less on fine-tuned measurement of what we already know about the developmental process and more on the formulation, testing, and continuous refinement of new theories of change to address significant threats in the early years of life. An exciting new era in early childhood policy, practice, and research lies at the convergence of these two agendas—an era driven by science, creativity, and pragmatic problem solving in the service of building a more humane present and more promising future for all young children and their families.

The Value of Reanalysis: TV Viewing and Attention Problems

E. Michael Foster and Stephanie Watkins
University of North Carolina

Using data from the National Longitudinal Survey of Youth (N = 1,159), this study reexamines the link between maternal reports of television viewing at ages 1 and 3 and attention problems at age 7. This work represents a reanalysis and extension of recent research suggesting young children's television viewing causes subsequent attention problems. The nonlinear specification reveals the association between television watching and attention problems exists—if at all—only at very high levels of viewing. Adding 2 covariates to the regression model eliminated even this modest effect. The earlier findings are not robust. This study also considers whether its own findings are sensitive to unobserved confounding using fixed-effects estimation. In general, it finds no meaningful relation between television viewing and attention problems.

Reanalysis is fairly common in other social sciences but relatively rare in psychology. Such analyses are often quite useful especially when the original analyses are provocative. For example, for at least three decades, demographers, economists, and sociologists have considered the impact of teenage childbearing on the lives of teen mothers and their children. Literally hundreds of studies have examined this issue, and many have focused on a handful of large, publicly available data sets, such as the Panel Study of Income Dynamics and the National Longitudinal Survey of Youth.

Our understanding of the phenomena has matured as analyses have continued. In the 1990s, provocative analyses of these data suggested that the effects had been grossly overstated and were likely small (Geronimus & Korenman, 1992); further analyses indicated that research in the 1980s and 1990s had indeed exaggerated the impact of teen childbearing but that the remaining costs were still substantial (Hoffman, Foster, & Furstenberg, 1993). Further analyses have continued to refine our understanding, emphasizing the factors that moderate the effect of early childbearing (such as a quick second birth; Kalmuss & Namerow, 1994).

This article accomplishes two purposes. First, we illustrate the importance of reanalysis with an example long of interest to developmentalists, the link between television viewing and children's behavior. A recently published article (Christakis, Christakis, Zimmerman, DiGiuseppe, & McCarty, 2004) suggests that television viewing is associated with attention deficit disorder. The first aim of this article is to reconsider whether the key findings are sensitive to modest changes in model specification. We do so by adding more covariates to the model and then by considering broader issues, such as unobserved confounding. We believe our findings demonstrate fairly convincingly that television viewing has no effect on attention problems, at least for the average child watching typical amounts of television.

The article's second contribution is to examine the effect of television viewing in a more nuanced manner. In particular, we consider whether the effect of television viewing depends on how much television a child watches using a tool underutilized in developmental research, semiparametric regression.

Semiparametric regression allows the researcher to model the effect of explanatory variables (television viewing and the potential confounding variables) on the outcome of interest, attention problems. The relation between the covariates and the outcome can be handled in one of two ways—as having a linear, parametric relation or as having a nonparametric relation. The latter involves fitting a smooth curve that can take virtually any form. That relation cannot be characterized with a single parameter estimate, but it can be plotted. These methods can be used to flexibly capture the association between variables without assuming a specific functional form and without capitalizing on chance

findings in the data. Such methods are increasingly common across a range of disciplines, such as biology (Huang et al., 2005), economics (Yatchew & No, 2001), health services research (Glick & Polsky, 1999), and others. We apply these methods here to assess the relation between television viewing and attention problems.

Nearly since the advent of television, researchers have been interested in its effects on children's cognitive and emotional development. In the 1960s, the National Institute of Mental Health (NIMH) commissioned $1 million worth of research projects that focused on various aspects of television and children's development (Liebert & Sprafkin, 1988). Much of that research examined the effects of television watching on children's ability to exercise self-control and maintain focus (Englander, 1997; Liebert & Sprafkin, 1988; Van Evra, 1998).

Surprisingly, very few studies have analyzed this question in large, national samples with appropriate demographic controls. A recent article by Christakis et al. (2004) spiked a resurgent interest in television's influence on children's attention and behavior. The authors assessed the link between television viewing at 1 and 3 years of age and attention problems at 7 years of age. The strengths of the study include its focus on very young children and the use of a large national sample. The authors reported a substantial—indeed, even alarming—link between early television watching and risk of attention problems at older ages. Given the levels of television viewing among children nationwide, such a strong relation would represent a major public health problem.

The Christakis et al. (2004) study raises several possibilities for reanalysis. First, the authors report only a linear analysis of the association between early television watching and later attention problems. The assumption here is that any additional hour of watching television yields the same increase in risk (i.e., in the log-odds of attention problems). Yet, research on television viewing finds that the context in which children watch television matters. Viewing behavior—duration (hours watched) and content (what is watched), with whom children watch (parents, peers, siblings), and how they watch (restricted, monitoring) are important factors to consider. The more television children watch, the more information they are exposed to and may process and retain, and the more they can replay their learned behavior (Potter, 1996; Valkenburg & Vroone, 2004; Van Evra, 1998). Bandura (2002) stated, "Heavy exposure to this symbolic world may eventually make the televised images appear to be the authentic state of human affairs" (p. 137).

Second, Christakis et al. (2004) included an array of covariates in their regressions, attempting to rule out spurious, third variable problems. Yet, they failed to include two available measures that we think are essential and are readily available in the data set. These two variables include a measure of mothers' achievement, assessed with the Armed Forces Qualification Test (AFQT), and a measure of the family's income. Mothers with lower levels of achievement or income may allow their children to watch more television, and these characteristics may influence behavior in later childhood. Whether the results Christakis et al. reported are robust to the additional inclusion of these two important variables represents a prime opportunity for reanalysis.

Method

Data

The data for these analyses and the original study were drawn from a large, nationally representative sample of children and their families followed longitudinally, the 1979 cohort of the National Longitudinal Survey of Youth (NLSY79). Participants in the original study were ages 14–24 in 1979, and as these women reached childbearing age, the study added an extensive battery of assessments involving their own children. Numerous analyses have used these data to consider a range of important questions involving children's development.

Of participants in the current study, 82% were non-Hispanic White, 6% were Hispanic, and 12% were African American when weighted (unweighted percentages were 62%, 14%, and 24%, respectively). In terms of socioeconomic status, 44% of participants reporting having a high school degree or less. (This figure was calculated with the sampling weights. The unweighted figure is 48%.) The sample is divided equally by gender.

The Christakis et al. (2004) study examined the link between television viewing between ages 1 and 3 and attention problems at age 7. Attention problems are assessed with the five-item hyperactivity subscale of the Behavior Problems Index, a maternal-report measure of children's behavior available in the data. We followed these authors in creating a binary classification representing attentional "problems" as either present or absent, using a cut-point of 120 on the same-gender standardized hyperactivity score. This procedure yields a prevalence for attentional problems that is similar to published reports of attention deficit hyperactivity disorder prevalence among young children in community samples (Wolraich, Hannah, Pinnock, Baumgaertel, & Brown, 1996).

Overview of Semiparametric Regression

Semiparametric regression is a special case of nonparametric regression. Nonparametric methods allow the researcher to examine the association between two variables without specifying the form of the relation a priori. Unlike parametric regression, which describes the relation of the data using a regression equation, nonparametric regression captures the relation using a smooth curve that can take virtually any shape. This relation can be described graphically. In essence, the curve represents a weighted, moving average of values of the dependent variable across the range of the explanatory variable.

Even though we are letting the data "speak for themselves," one must be cognizant of not underfitting or overfitting the association. A span parameter, the percentage of data points used to calculate the moving average, is set for the model to address this issue. Past experience suggests that if the parameter is too low (0.15–0.35), the graph may display excessive noise. If the parameter is set too high (0.75–1.00), important fluctuations in the data may be missed. An intermediate span of 0.65 is suggested as a compromise between these two extremes (Jacoby, 2000).

In our application, we used a semiparametric version of this model that allowed us to include key covariates in a nonparametric manner and then to control for other covariates as linear predictors. In our case, the group of covariates entered linearly were those we were interested in not for their own sake but as potential confounders (such as family income; Fox, 2000) We included these variables parametrically in order to provide the readers with a parametric estimate of the link between that covariate and the outcome.

The semiparametric model is not only a descriptive tool but also can be used to draw statistical inference. Partial F tests are available to test for nonlinearity of selected covariates as well as interaction between covariates. By contrasting two models where one covariate enters linearly and the other enters nonparametrically, one can derive an F statistic to test for the significance of a partial nonlinear relation. This principle is extended to test for the significance of interaction terms (Fox, 2000). (Note that we might have included key covariates [like family income] nonparametrically as well. Doing could be expected to further diminish the predictive power of television viewing. If the residual relation between television viewing and attention problems had remained significant, we would have explored these models. As illustrated below, simply including the covariates linearly was enough to make the putative effect of television viewing disappear.)

Results

Replicating the Results in Christakis et al. (2004)

We start by following the methods described in Christakis et al. (2004) to replicate the authors' findings (and correcting for minor problems in the original analysis). We obtain sample sizes, means, and standard deviations for the key variables that are nearly identical to those in Christakis et al., and when dissimilar, differ only in the first decimal place.

Our "age 1" sample was 1,288 children (compared to 1,278 as published in the Christakis et al., 2004, report), while our "age 3" sample was 1,404 (compared to 1,345). One difference in our methods is that we used the sampling weights for the year 2000 for all of the children in the study instead of using the sampling weights from the year the outcome was measured as in the original study. (While the effect on the parameter estimates was negligible, using the weights from a single wave of data collection produces results that are more clearly representative of the population sampled.) Doing so decreased the sample size for the "age 1" regressions to 1,039 children and the "age 3" regressions to 1,159.

We next replicated the multivariate logistic regressions presented in the original article. The odds ratios for the continuous measure of television viewing in the regressions are shown in Models 1 and 3 of Table 1. At both ages 1 and 3, the effect of an additional hour of daily television on the probability of attention problems is very small—one half of 1%.

These largely replicate the results presented in the original report (Christakis et al., 2004, Table 2). These findings suggest that our sensitivity analyses began at the right starting point—the estimates in the original study.

Table 1
Odds Ratios for Various Regression Analyses

Note. These analyses use 2000 sampling weights for the children. Odds ratios (OR) are presented with robust standard errors (*SE*) below in parentheses. Also reported are the marginal effects (ME) of the covariate on the predicted probability of attention problems. For the models labeled "original covariates," covariates include child gender and age, race, gestational age of child, alcohol and tobacco consumption during pregnancy, number of children in household, presence of two parents, cognitive stimulation and emotional support scores, mother's age, urbanicity, year fixed effects, maternal education, maternal depression, and maternal self-esteem. The "extended covariates" include mother's Armed Forces Qualification Test score and family poverty status.
$^{\dagger}p < .10$. $^{*}p < .05$.

Extension: Adding More Covariates

Our first concern with the initial analyses involved the role of various family factors that might be confounded with the effect of television watching. The NLSY79 data are particularly well suited to these analyses because they provide extensive information on the children's development and their environment. These analyses involved a series of regressions that controlled for additional background characteristics of the mother: her academic achievement and a measure of family income. Mothers' academic achievement was measured with the AFQT percentile score. The AFQT, which was administered to NLSY sample members in 1980, assesses paragraph comprehension, arithmetic reasoning, word knowledge, and mathematics knowledge. The AFQT is described by

Neal and Johnson (1996) as a measure of basic skills, or human capital, attained. While the original analysis controls for maternal education, the AFQT is an important measure of maternal skills and may be an important influence on how much television the mother allows the child to watch.

Second, we include a measure of the poverty status of the family at ages 1 and 3 in the respective regressions. Poverty status captures a family's ability to purchase the resources and goods (e.g., schools, housing, food, safe, and cognitively enriched learning environments) that are critical for successful development. It may also be an important influence on how much television the child is allowed to watch.

In the age 1 regressions, once these two characteristics of the mother and the family were included, the continuous measure of television viewing (i.e., as in the original analysis) was no longer statistically significant (compare Model 1 vs. Model 2). Models 3 and 4 report similar analyses for television viewing at age 3.

Extension: Fixed-Effects Estimation and the Potential for Unobserved Confounding

The analyses presented above consider the effect of television viewing conditional on observed family factors. As a reviewer noted, it seems quite possible (if not likely) that our list of covariates is incomplete and that other third factors remain—these might involve characteristics of the child, his or her family, and/or his or her neighborhood that affect television viewing and attention problems. These variables likely are positively correlated with both television viewing and attention problems—i.e., if anything we suspect the estimate we have reported above is an overestimate.

However, because these other confounders are unmeasured or omitted, whether and how they influence the observed relation between television viewing and attention problems is unknown. Some unobserved factor, however, may encourage television viewing yet reduce attention problems. In that case, the effect estimated here may underestimate the effect of television viewing.

While unobserved factors cannot be measured, they can be accounted for in estimation. One way to do so involves fixed-effects estimation (Greene, 2008). That method has been used in a range of developmental analyses (e.g., Foster & Kalil, 2007). In essence, this method allows each child to have his or her own intercept. As a result, the relation between variables is based on *within-child*, intertemporal variation only. As a result, this method effectively eliminates cross-child variation in unobserved, time-invariant factors that may confound the relation of interest.

We conducted such analyses using data from ages 1, 3, 5, and 7. We examined the effect of lagged television viewing on attention problems. For these analyses, we used an extension of the model structure employed above—in particular, we used the twice-lagged measure of television viewing (from ages 1 and 3) to explain the outcome two waves later (ages 5 and 7). In essence, this method involves assessing the effect of the change in early television viewing between ages 1 and 3 on the change in attention problems between ages 5 and 7. The analysis also included changes in other time-varying characteristics as regressor (such as the change in poverty status). Estimation was performed using fixed-effects logistic regression. (We also conducted the analyses with once-lagged television viewing, and the results were unaffected.)

In the fixed-effects model, the point estimate of the effect of television actually was negative (–.04). The effect implies that television viewing may reduce attention problems but was not statistically significant (p = .32). (The implied marginal effect was roughly comparable to that in the earlier analyses.)

To some extent, the lack of significance is driven by a lack of power—statistical power in the fixed-effects regression is driven by individuals who change values on the explanatory and dependent variables over time. For a fairly stable construct, like attention problems, power is limited. (The reported standards are not incorrect, just larger.) Power was sufficient enough, however, to reject the null hypothesis that the random- and fixed-effects estimates were equivalent. (This test is known as the Hausman test.) Rejection in this case suggests that the random-effects estimates are indeed biased by unobservables—in this case, suggesting that other child and family disadvantages are correlated with television viewing and inflate its effect in standard analyses (like those in the original Christakis et al., 2004, article).

Note that because these analyses relied on all waves of data, we analyzed multiply imputated data to preserve cases. In doing so, we assume the data are missing at random with regard to both the measured covariates and the time-invariant unobservables (Foster, Fang, & the Conduct Problems Prevention Research Group, 2004). We used Rubin's rules to combine the estimates from three imputations. (Little & Rubin, 1987, 2002). In imputing the data we preserved the hierarchical structure of the data (i.e., the nesting of time points within individuals) by imputing a "wide" file—that is, by treating each wave's variables as a separate variable on a single, individual-level record.

Extension: Nonlinear Effects of Television Viewing

Our analysis described the bivariate relation between early television exposure and attention problems with a semiparametric additive model. This model allowed us to enter television viewing without an underlying functional form while still having the flexibility to include linear covariates. The smoothing parameter was set at 0.65.

The semiparametric model revealed a minimal linear increase in attention problems as average daily television viewing increased from 5 to 15 hr while controlling for all other linear covariates in the model (see Figure 1). However, the estimate was less precise for the upper levels of television viewing. The majority of the data, represented by tick marks on the horizontal axis, were located between approximately 0 and 8 hr of television viewing. Thus, the 95% confidence band, which is a measure reflecting the precision of the behavioral score estimate, was quite large for children exposed to greater than 5 hr of television.

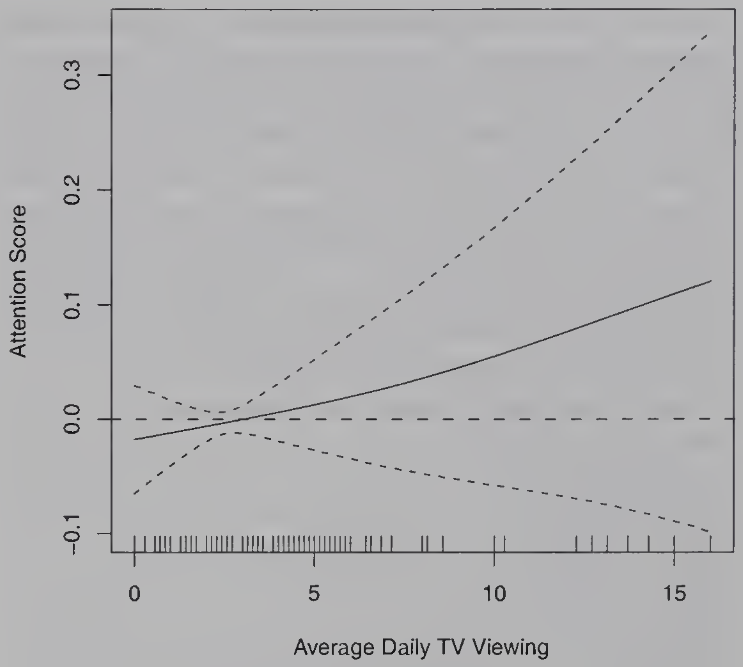

Figure 1. Semiparametric analysis of the association between average daily television viewing and attention problems. These data taken from the 1979 cohort of the National Longitudinal Survey of Youth represent a smooth function summarizing the dependence of attention score on average daily television while controlling for covariates linearly. Covariates for alcohol and tobacco were combined to fit the model on the logit scale. No differences in the plots were observed when these covariates were fit independently or combined using the normal scale.

The results of the semiparametric estimation allowed us to test selected hypotheses. First, when comparing the fully linear and semiparametric models, the test of nonlinearity was not statistically significant (p = .10). That is, we could not reject the null hypothesis that television viewing has a linear effect. However, we also were unable to reject the null hypothesis that television has no effect at all (p = .10). One also can see that even at high levels of television viewing the confidence band includes zero (no effect). As one would expect the size of the band broadens at higher levels of viewing because of the limited number of observations at those levels.

Table 2 presents the full set of estimates for this model. The estimates include the parametric estimates for those covariates included parametrically. These estimates were used to adjust the outcome for the effect of these covariates.

Table 2
Semiparametric Model: Parameter Estimates

Variable	Parameter estimate	Standard error	*p* value
Boy	0.56	0.45	.22
Black	−1/50	0.96	.12
Hispanic	0.50	0.63	.43
Child's age	0.01	0.07	.92
Mom's age	−0.04	0.12	.74
Mom's education	−0.14	0.12	.23
Children in the household	−0.55	0.27	.04*
Two-parent household	0.55	0.80	.49
Gestational age	−0.05	0.13	.73
Self-esteem	−0.06	0.06	.28
Depression	0.02	0.03	.49
Alcohol, tobacco	0.42	0.32	.19
Urbanicity (omitted category)			
Urbancity A	−0.19	0.79	.81
Urbancity B	−1.42	0.74	.05
Urbancity C	−2.01	1.14	.08
Year (omitted category)			
1996	1.43	2.27	.53
1998	2.13	2.27	.35
2000	2.10	2.46	.39

Note. All estimates rounded to two decimal places.
$^*p < .05$.

Discussion

More young children, that is, infants, toddlers, and preschoolers, watch television today. American children in particular watch a lot of television: on average 2.2 hr per day at age 1 and 3.6 hr by age 3 (Christakis et al., 2004). The American Academy of

Pediatrics has recently recommended that children under 2 watch no television and that older children's television watching be limited (American Academy of Pediatrics, 2001). There are many good reasons to think that this idea is a good one. For example, the time that children spend watching television might more productively be spent in less sedentary activities. Our work, however, questions the claim that television viewing causes a serious mental disorder, attention deficit disorder.

Our reanalyses produced two main findings. First, the association between early television watching (at ages 1 and 3) and risk of attention problems measured at age 7 is significant—if at all—only for the small group of children (10%) of the sample who watch 7 or more hr of TV per day. In other words, the relation is nonlinear, and it is not true, as Christakis et al. (2004) were quoted in the print media as saying, that each extra hour of television viewed per day is associated with a 10% increased likelihood of developing attention problems later on. Modest levels of television viewing do not appear to be detrimental, even for young children.

Second, and even more importantly, our analyses reveal that even this relation becomes nonsignificant once comparisons of children watching differing amounts of television are adjusted for two additional factors. In particular, we estimate regressions that control for maternal academic achievement and the child's poverty status in early life.

Both of these characteristics increase the likelihood that children watch more television and also influence child outcomes. As a result, analyses that ignore these relation confound the effects of television watching with that of these other factors. For example, mothers who are less oriented toward academic achievement might be more likely to allow their young children to watch TV in lieu of more enriching activities. Poor children might have fewer opportunities to participate in activities outside the home, and they, too, might be more likely to watch TV. As a result, the effects of poverty are mistakenly attributed to television watching.

We recognize that both the original study and this study may neglect the role of nonlinearities. For these analyses, we rely on semiparametric regression to capture the association between early television exposure and attention problems. These analyses provide little evidence of a link between attention problems and television viewing, linear or otherwise. We consider whether and how the amount of television viewing matters using semiparametric methods. Those analyses suggest that the linear model fits the data adequately—there was no relation between television viewing and attention problems. The lack of a relation between television viewing and attention problems in our linear model did not mask a nonlinear relation.

Christakis et al. (2004) conclude that "the magnitude of the risk associated with television viewing . . . is clinically significant." The analyses presented here suggest that the relation between television viewing and behavior is complex, *but the weight of the evidence suggests that reports of a strong relation were premature.* If there are effects of television viewing, they occur principally at high levels with the probability of effect varying between age groups. The average 2- to 17-year-old watches 2.8 hr of television per day, and the average American watches just over 4 hr per day Center for Screentime Awareness, n.d.). We find negative effects of television viewing occur only at much higher levels.

It is worth noting that there are potential statistical problems that may mask the negative effects of television viewing. For example, the measure of television viewing was reported by mothers, and those reports may not be especially accurate. In that case, measurement error would work to attenuate estimates of the parameter of interest. However, social desirability may lead parents to underreport the amount of television their children watch. If more advantaged parents are more embarrassed by how much television their children watch, then maternal reports would be negatively correlated with parental advantage. In that case conventional analyses like those in the original study would overestimate the effect of television.

Data problems may further mask the effect of television viewing. As discussed above, the effect of television may depend on the "quality" of viewing—with whom, the content of the shows, and so on. Some research suggests these dimensions of viewing may matter as much as quantity. When Wright examined television content and educational skills, children who watched educational television actually had *higher* school readiness and language skills. Yet children who frequently viewed general programming performed more poorly on these measures (Wright et al., 2001). Christakis et al. (2004) also assessed the effect of television content on children's behavior; exposure to violent content posed a significant risk of antisocial behavior later in childhood. Of course, these studies are only suggestive at this point. They suffer from the same methodological limitations as research into the quantity of television viewing, and the selection issues are at least as great.

A standard assessment of omitted variable bias suggests that our estimate of the effect of quantity is the effect of quantity per se plus the effect of quality times the association between quality and quantity (Greene, 1993). In other words, if children who watch more television watch *worse* television, then the effect estimated here captures the effect of both quality and quantity. In that sense, our estimate may exaggerate the effect of the quantity of television per se (i.e., is greater than the effect of quantity holding quality constant). That effect is small, but television may remain detrimental for children who watch a lot of certain types of television.

Clearly, our understanding of the effects of television viewing is still evolving, and so the broader lessons from this article do not involve the effect of television viewing per se. Our intent is to highlight the importance of reanalysis and data sharing so that researchers may strengthen the knowledge base for social science more generally. When research findings that have the potential to influence public health policy are translated into guidelines for parents, and/or affect parental beliefs, reanalysis is vital to ensure that the findings are robust. Transparency of data methods and results ensures confidence in study findings and prevent misleading media coverage.

Counterfactual Reasoning: Developing a Sense of ''Nearest Possible World''

Eva Rafetseder, Renate Cristi-Vargas, and Josef Perner
University of Salzburg, Austria

This study investigated at what point in development 3- to 6-year-old children begin to demonstrate counterfactual reasoning by controlling for fortuitously correct answers that result from basic conditional reasoning. *Basic conditional reasoning* occurs when one applies typical regularities (such as ''If 'whenever' it doesn't rain the street is dry'') to counterfactual questions (such as ''If it had not rained, would the street be wet or dry?'') without regard to actual events (e.g., if street cleaners had just been washing the street). In *counterfactual reasoning*, however, the conditional reasoning must be constrained by actual events (according to the ''nearest possible world''). In situations when counterfactual reasoning and basic conditional reasoning would yield the same answers, even the youngest children gave mostly correct answers. However, tasks in which the 2 reasoning strategies resulted in different answers proved unusually difficult even for the older children.

People often reflect on how an event in the past might have turned out differently. Creating such alternatives to known facts is called counterfactual reasoning (Roese, 1997). Although it is common among adults, it is still not clear what is necessary for proper counterfactual reasoning. This is a serious shortcoming because counterfactual reasoning is relevant in many different areas such as cognitive psychology, social psychology, developmental psychology, and philosophy.

Developmental psychologists have addressed this issue by exploring whether children's counterfactual reasoning abilities are related to their understanding of causation (German, 1999; Harris, German, & Mills, 1996; Kavanaugh & Harris, 2000), their understanding of false belief (Grant, Riggs, & Boucher, 2004; Guajardo & Turley-Ames, 2004; Müller, Miller, Michalczyk, & Karapinka, 2007; Perner, Sprung, & Steinkogler, 2004; Riggs, Peterson, Robinson, & Mitchell, 1998), their feeling of regret and relief (Amsel & Smalley, 2000; Amsel et al., 2003; Guttentag & Ferrell, 2004), their understanding of counterfactual and actual worlds as alternative possibilities at a certain time in the past (Beck, Robinson, Carroll, & Apperly, 2006; Byrne, 2005), or their executive functions such as inhibitory control (Beck, Riggs, & Gorniak, 2009) and working memory (German & Nichols, 2003; Robinson & Beck, 2000).

The majority of these developmental studies assessed the ability to reason counterfactually by telling a short story (e.g., ''Carol made the floor all dirty with her shoes'') and then asking a subjunctive question about the past (or present): What if Carol had taken her shoes off—would the floor be dirty? (Harris et al., 1996). Children's main error was to answer with what was actually the case in the story, that is, that the floor was dirty (referred to as a ''reality error''). The predilection for reality errors subsides between 3 and 5 years, although the exact age varies across studies. However, in studies that assessed the reasoning differently (such as showing counterfactual emotions like regret), children showed difficulties with some counterfactual tasks until 6 years or older (Amsel et al., 2003; Amsel & Smalley, 2000; Beck et al., 2006; open counterfactuals; Guttentag & Ferrell, 2004). This discrepancy reveals a shortcoming in existing studies: They fail to distinguish between the kind of reasoning the experimenter intended to investigate and the kind of reasoning the children employed.

Answering a subjunctive past question correctly shows that children can reason with conditionals (e.g., if X is F then Y is G) and that they can do so independently of what the actual states of X and Y

We would like to express our appreciation to the heads and children of the following kindergartens for their cooperation and valuable time participating in this project: Betriebskindergarten St. Johanns-Spital, Pfarrcaritaskindergarten Gallneukirchen, Vereinskindergarten Perg Haydnstraße, and Vereinskindergarten Perg Friedhofstraße. This research was financially supported by Austrian Science Fund project (I140-G15) ''Counterfactual Reasoning in Children'' as part of the ESF EUROCORES LogiCCC initiative and forms part of the doctoral dissertation of Eva Rafetseder in the Department of Psychology at the University of Salzburg.

are. This demonstrates an ability to entertain counterfactual states, but that ability is not the same as counterfactual reasoning. All *kinds* of conditional reasoning can depend on assumptions that are not currently true; this is not limited to counterfactual reasoning. For instance, the developmental literature considers a question about the future—"If X will be F then Y will be . . .?"—to demand future hypothetical reasoning (Riggs et al., 1998), and studies have consistently found these questions to be much easier than subjunctive questions about the past. Another kind of conditional, rarely discussed in the developmental literature, is the universally quantified conditional expressing a general regularity, which is typically formulated in the present tense indicative. "If X is F then Y is G" can be read to mean that whenever X is F then Y is G, without reference to any particular instance at a particular time. Reasoning with such universals demands what we call "basic conditional reasoning."

The problem with previous investigations is that although they used a subjunctive past question, children might have applied basic conditional reasoning and arrived at the same answers. For instance, when an investigator asks out of the blue, "If Carol had taken off her shoes, would the floor be dirty or clean?" a child could answer with "(probably) clean" by use of basic conditional reasoning, applying "If 'whenever' people take off their shoes floors tend to stay clean" to the case of Carol. Children often interpret experimenters' instructions not as intended but in a pragmatic way. For instance, Rumain, Connell, and Brain (1983) pointed out that children interpret "if" pragmatically. They often interpret the statement "If you mow the lawn, then I will give you five dollars" to mean "If you do not mow the lawn, then I won't give you five dollars." In other words, they try to figure out what the speaker actually means by the sentence. On the basis of these assumptions, they draw conclusions, for example, that if they do not mow the lawn, they will not earn money. Although this conclusion is not logically valid, it would be true in most situations. Basic conditional reasoning is, of course, only a minimal instance of reasoning because it consists of two simple processes: (a) memory retrieval, which is at best a prerequisite for logical reasoning (Markovits & Barrouillet, 2002), not an act of reasoning in itself, and (b) the simple logical reasoning rule of universal instantiation.

What abilities do children need to demonstrate proper counterfactual reasoning? Lewis (1973) proposed that, unlike normal conditionals whose truth depends on the real world, the truth of counterfactual claims is determined by what is true in the *nearest possible world* (that which resembles the real world most closely). Consider the sentence "If Carol had taken her shoes off, the floor would have stayed clean." This is true only if, in a possible world in which Carol had taken her shoes off (but is otherwise as similar as logically possible to the actual world), the floor would have stayed clean. The counterfactual claim is false if there is some nearer possible world, where Carol removed her shoes but the floor was still dirty—if, for instance, before Carol entered the room with her dirty shoes, her nasty brother had already messed up the floor with *his* dirty shoes. Hence, in this nearest possible world, even though Carol takes off her shoes, the floor is still dirty. With counterfactual reasoning, we would thus conclude that the floor would have been dirty, a conclusion that basic conditional reasoning would not have produced. We think that developmental investigations must distinguish more clearly between counterfactual and basic conditional reasoning.

There is consistent evidence in the developmental literature that children become capable of answering indicative future questions (requiring future hypothetical reasoning) before 3 years of age. This is reliably earlier than they can answer past subjunctive questions (Beck et al., 2006; Perner et al., 2004; Riggs & Peterson, 2000; Riggs et al., 1998; Robinson & Beck, 2000; Study 1), which tend to elicit the reality error. There are several points of difference that may make counterfactual reasoning particularly difficult, especially for children. First, the counterfactual assumption, by definition, contradicts with the corresponding fact (Carol took her shoes off—Carol was wearing her shoes), whereas in future hypothetical reasoning the corresponding fact in the future is not yet known. Second, the use of the subjunctive mood signals that the real sequence of events cannot be ignored, but must play a role in the counterfactual reasoning process. This requires that two different models of the world stay simultaneously active (Beck et al., 2006; Byrne, 2005), which requires more information-processing capacity and is likely to intensify the interference of known facts with counterfactual assumptions more than if hypothetical assumptions happen to differ from reality. Researchers have amply documented the problems created by the interference of reality with the process of counterfactual assumption and conclusion for very young children of 2½–5 years (Beck et al., 2006; Perner et al., 2004; Riggs & Peterson, 2000; Riggs et al., 1998; Robinson & Beck, 2000, Study 1). Finally, the real sequence of events that is being counterfactually altered must be kept active for a good reason. It plays an important role in how the counterfactual model needs to be constructed, which developmental psychology has yet to investigate but is hotly debated in philosophy.

The last point may especially explain the existing discrepancy in study results about the onset of counterfactual reasoning. Children master some counterfactual problems (past subjunctive questions) very early, at the age of 3½–4½ years (Beck et al., 2006; standard counterfactuals, German, 1999; German & Nichols, 2003; Harris et al., 1996; Perner et al., 2004; Riggs et al., 1998), but some investigations show little sign of counterfactual thinking before the age of 6 years (Amsel et al., 2003; Amsel & Smalley, 2000; Beck et al., 2006; open counterfactuals, Guttentag & Ferrell, 2004).

One way of making sense of these discrepancies is to assume that even the youngest children are able to reason counterfactually but are prevented from showing their prowess on more difficult problems; scholars have suggested two possible reasons for this. One is that children (German, 1999; Guttentag & Ferrell, 2004), like adults (Roese, 1997), tend to be more likely to engage in counterfactual reasoning for negative outcomes than for positive outcomes. However, Kavanaugh and Harris (2000; Harris, 2000) tested this hypothesis directly and found no difference in children's ability to use counterfactual reasoning for negative and positive outcomes. The other suggestion comes from German and Nichols (2003), who provided evidence that because of children's working memory limitations, the length of the inferential or causal chain from the counterfactual assumption to the predicted outcome affects children's ability to engage in counterfactual reasoning.

In contrast, Perner and Rafetseder (in press; Perner, 2000) worked from the premise that younger children *cannot* reason counterfactually and suggested that these children's correct answers to past subjunctive questions might be based on basic conditional reasoning (using our terminology). Depending on the particular task, children were more or less likely to make suitable background assumptions leading to the same answer that counterfactual reasoning would produce, which made their answers look like evidence for counterfactual reasoning. The early use of basic conditional reasoning may explain why some studies show little sign of counterfactual reasoning before the age of 6 years, provided that we can show that counterfactual reasoning takes the nearest possible world constraint into account. To provide more decisive evidence for counterfactual reasoning in children, we designed stories in which counterfactual reasoning produces different answers than basic conditional reasoning does.

Experiment 1

The principal objective of this study was to determine whether children can answer "counterfactual" subjunctive questions about a past event correctly when a basic conditional reasoning approach yields a different answer. We used two different story worlds, the *sweets story* and the *dwarf story*. In each story world, four different sequences of events could take place, and each sequence comprised two component events, in this case, two transformations of an object's location. For instance, in the sweets story, mother puts sweets regularly on either the top shelf or the bottom shelf (the first transformation), and then either the tall boy or the little girl comes looking for the sweets and then takes them into his or her room (the second transformation). The tall boy can reach both shelves, so he can take the sweets into his room regardless of where mother puts them. The little girl, however, is too short to reach the top shelf and can reach only the bottom shelf. Thus, if she comes looking for the sweets, either they will remain on the top shelf or she will take them from the bottom shelf into her room. Figure 1 shows the particular structure of these story worlds.

We can see that in the case of the girl looking for the sweets, the subjunctive past question about the boy, "If not the little girl but the tall boy had come along looking for sweets, where would the sweets be?" gives the correct answer "in the boy's room." This answer would also result from basic condi-

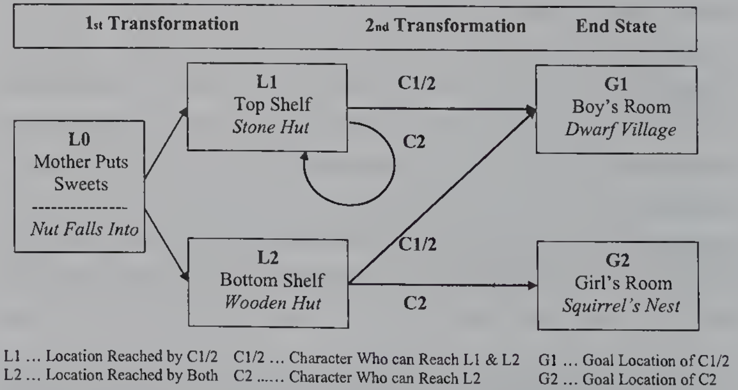

Figure 1. Structure of story worlds in Experiment 1.

tional reasoning: "If 'whenever' the boy comes looking for the sweets, they end up in his room." However, matters are different in the complementary cases in which we ask a subjunctive past question about the girl. Children who are aware of the counterfactual nature of the question—those who know to be selective of the different possible worlds—would answer with "in her room" when sweets had been on the bottom shelf but with "on the top shelf" when sweets had been there. In contrast, children using basic conditional reasoning, despite the subjunctive mood of the question, will give the same answer in both cases, whether the sweets were on the top or the bottom shelf. What their answer will actually be depends on which background assumptions they are more likely to make. If they assume that the sweets are where the girl can reach them, the completion of "If 'whenever' the girl comes looking for sweets, . . ." is ". . . they end up in the girl's room" regardless of where they had been at the beginning. However, when the background assumption is that the sweets are where the girl cannot reach them, then the consequent is that the sweets will be on the top shelf. We do not yet know what background assumptions children are likely to make, as this remains an empirical issue. However, whatever they prefer, as a result of the fixed background assumptions, they should give the same answer in both cases, regardless of where mother puts the sweets. Importantly, this means that we can distinguish between children who employ counterfactual reasoning and those who apply basic conditional reasoning to answer our subjunctive past questions.

Method

Participants. The sample consisted of 33 children (15 boys, 18 girls) from three different nursery schools in the area of Salzburg and Upper Austria, between the age of 2;11 (years; months) and 5;9. The children had a mean age of 4;4 with a standard deviation of 9 months. For the later analysis, the overall sample was split into two age groups. The age of the 16 children in the younger group ranged from 2;11 to 4;4 (M = 3;8, SD = 0;4), and the 17 children in the older group were between 4;5 and 5;9 (M = 4;11, SD = 0;6).

Materials. We used two different wooden models built on 42 × 30 cm wooden platforms. The model for the sweets story consisted of a cupboard with a shelf centrally placed and two boxes, a brown one standing on the shelf and an orange one standing beneath the shelf. For acting out the story, we used sweets and two dolls, a female one and a male one twice as tall as the female one. Each doll had its own room including a table and a photo of itself.

The model for the dwarf story consisted of two huts, one made of wood and one made of stone, and a large walnut tree standing behind the huts. For acting out the story, we used walnuts, a dwarf, and a squirrel. The dwarf lived in the dwarf village (three houses were drawn on a piece of cardboard) and the squirrel lived in a nest in another tree.

Design. We tested all children in two sessions approximately 2 days apart; sessions lasted about 15 min. We administered the two story worlds and the four different event sequences in each story world in fully counterbalanced order, and both story worlds were administered in each session. We tested children with a total of eight indicative future questions and eight subjunctive past questions. In fact, all eight subjunctive past questions required counterfactual reasoning, but children could get away with basic conditional reasoning for six of the subjunctive past questions: In Conditions 2 and 4 (see Table 1) and in either Condition 1 or 3, it is not yet clear which one of the two conditions the children will favor, as this depends on the background assumptions children make.

Table 1

Expected Answers for Each Reasoning Strategy in the Four Conditions of Experiment 1

	Actual events		CF change		Reasoning strategy	
Condition	First transf.	Second transf.	End state	Second transf.	CF	BC
1	L1	C1/2	G1	C1/2 → C2	L1	? (L1, G2)[a]
2	L1	C2	L1	C2 → C1/2	G1	G1
3	L2	C1/2	G1	C1/2 → C2	G2	? (L1, G2)[a]
4	L2	C2	G2	C2 → C1/2	G1	G1

Note. "x → y" indicates that the real event x was replaced by the counterfactually assumed event y, that is, "if not x but y had happened." The original German version for the indicative future question was: "Was passiert mit den Zuckerl wenn jetzt der Simon kommt und nach Zuckerl sucht?" and for the past subjunctive question: "Aber, wenn nicht der Simon sondern die kleine Julia nach Zuckerl gesucht hätte, wo wären denn dann die Zuckerl?" Transf. = transformation; CF = counterfactual; BC = basic conditional; L1 = sweet is on the top shelf/nut falls into the stone hut; L2 = sweet is on the bottom shelf/nut falls into the wooden hut; C1/2 = boy/dwarf comes along; C2 = girl/squirrel comes along; G1 = boy's room/dwarf village; G2 = girl's room/squirrel's nest.

[a] No prediction about which of the two answers children will give, but they should give the same in both conditions.

Procedure. We tested each child in a quiet area away from the other children. We explained the sweets story as follows: These are Simon and his little sister Julia. Both like sweets very much. When their mother buys sweets, she puts them *either* in a box on the top shelf *or* in a box on the bottom shelf. The boy can reach both shelves. Look, when he finds some sweets he brings them into his room. His little sister is not tall enough to reach the top shelf. She can only reach the bottom shelf. If she finds some sweets, she brings them into her room.

The dwarf story is about a dwarf who lives in a dwarf village and a squirrel that lives in a nest in a tree. Both like nuts very much. In search of nuts, they come to a nut tree under which two huts are built. In the roof of each hut there is a tiny hole through which nuts fall inside. The dwarf can open the door of each hut to get in, collect the nuts, and bring them to his village. The squirrel, unfortunately, cannot open the doors of the huts. However, through a hole in the wooden hut, it can squeeze inside to collect the nuts and bring them to its nest.

Children had to answer a total of seven control questions per story world to ensure that they had remembered all details, such as (1) Which one is the boy's room? (2) Which one is the girl's room? (3) From which shelf can the boy take sweets? (4) Where does he bring the sweets? (5) From which shelf can the girl take sweets? (6) Where does she bring the sweets? (7) Why is the girl unable to take the sweets from the top shelf? Examiners corrected wrong answers and familiarized the children by repeating the story (two times at maximum) until they answered all control questions correctly.

After the children became familiar with the structure of a story world, testing started with different events, resulting from the combination of where the object of desire was located (L1, L2) and which character came to collect it (C1/2, the character that can reach each location, and C2, who can reach only Location L2). For each event, we asked indicative future and subjunctive past questions. For instance (Condition 1): "Today the box on the bottom shelf is empty. There are only sweets in the box on the top shelf." At this point, we asked the children the following questions:

> MEMORY 1: "Where are the sweets now?"
>
> INDICATIVE FUTURE: "What will happen to the sweets when the boy comes looking for sweets?"

After the child has given an answer, this event is played out: "Look! This time the boy comes along, looking for sweets. He finds them in the box on the top shelf and takes them to his room!"

> MEMORY 2: "Where are the sweets now?"
>
> SUBJUNCTIVE PAST: "But what if not the tall boy but the little girl had come along looking for sweets, where would the sweets be?"

Table 1 shows the expected answers for each condition depending on whether children use counterfactual or basic conditional reasoning to answer the subjunctive past question.

Results

Control and memory questions. The children answered the different control and memory questions almost perfectly (above 95%) on the first trial. They appeared to have a good understanding of how the story structure worked. We checked that the exclusion from our analysis of children who answered incorrectly had no influence on our results.

Indicative future questions. Performance on the indicative future questions of the sweets story (94% correct) and dwarf story (96% correct) was not significantly different, Wilcoxon signed ranks test: $Z(N = 33) = -1.0$, $p = .32$, Cohen's $d = 0.17$. Eleven children made one mistake (out of eight questions); thus, they answered 253 of 264 questions (almost 96%) correctly. However, there was a significant difference between the four conditions (see Table 1) that asked indicative future questions, Friedman test: $\chi^2(3,\ N = 33) = 27.4$, $p < .01$, $\eta_p^2 = .28$. The children made 10 mistakes in Condition 2, where the character C2 could not reach the item in Location L1, such as when mother had put the sweets on the top shelf: "What will happen with the sweets now, when the little girl comes looking for sweets?" The younger children in particular had some difficulty in understanding that the sweets would stay on the top shelf. Nevertheless, they answered 75% of the indicative future questions in Condition 2 correctly—every child answered at least one of the two questions correctly—compared to the older group, who answered 87.5% of the questions correctly. Clearly, most of the younger and practically all of the older children understood that the item stays in L1 when the C2 character comes. Children who answered only one of these indicative future questions correctly did not perform significantly differently on the corresponding subjunctive past question (the tall boy had come to take the sweets from the top shelf L1 to his room: "What if not the tall boy but the little girl had come along, where would the sweets be?"—in L1) from those children who answered both of the indicative future questions correctly, Mann–Whitney test: $U(n_1 = 10, n_2 = 23) = 100$, $p = .24$, Cohen's $d = 0.43$. We checked that exclusion of the 10 children who answered the indicative future question of Condition 2 incorrectly had no influence on the interpretation of results.

Subjunctive past questions. Children had noticeably more problems with the subjunctive past questions, where they gave correct answers to 55% of the questions in the sweets story and 46% in the dwarf story, Wilcoxon signed ranks test: $Z(N = 33) = -1.5$, $p = .13$, Cohen's $d = 0.28$. Thus, they answered only 50% correctly compared to 96% of the indicative future questions, Wilcoxon signed ranks test: $Z(N = 33) = -5.0$, $p < .01$, Cohen's $d = 2.34$. However, performance is above chance if we consider the chance level to be at 25% (four possible answers: L1, L2, G1, and G2). The older children gave more (58.8%) correct answers than the younger children (42.1%), Mann–Whitney test: $U(n_1 = 16, n_2 = 17) = 63$, $p < .01$, Cohen's $d = 0.89$. Figure 2 shows children's performance on the subjunctive past questions, split up by the four different conditions (averaged over the two story worlds).

We found that particular conditions had significant effects in the subjunctive past questions, Friedman test: $\chi^2(3, N = 33) = 53.9$, $p < .01$, $\eta_p^2 = .55$. Condition 1 differed significantly from all the other conditions, Wilcoxon signed ranks test for Condition 2: $Z(N = 33) = -4.8$, $p < .01$, Cohen's $d = 1.81$; for Condition 3: $Z(N = 33) = -4.4$, $p < .01$, Cohen's $d = 1.28$; for Condition 4: $Z(N = 33) = -4.6$, $p < .01$, Cohen's $d = 1.54$; but Conditions 2, 3, and 4 did not differ significantly from each other, Wilcoxon signed ranks test for Conditions 2 and 3: $Z(N = 33) = -1.8$, $p = .07$, Cohen's $d = 0.31$; for Conditions 2 and 4: $Z(N = 33) = -1.0$, $p = .3$, Cohen's $d = 0.17$; for Condition 3 and 4: $Z(N = 33) = -1.2$, $p = .3$, Cohen's $d = 0.20$.

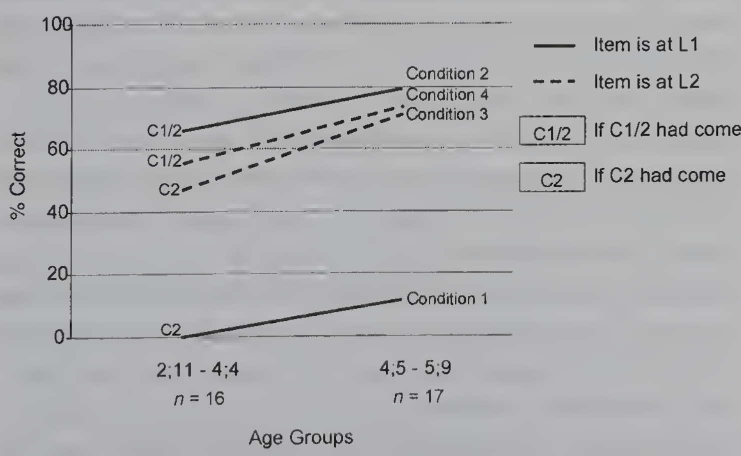

Figure 2. Counterfactual reasoning performance on the four different conditions in Experiment 1.

Our results show that children had severe difficulties, especially with subjunctive past questions where the C2 character could not reach the sweets at L1 (Condition 1): For example, mother has put the sweets in the top shelf (L1), and the boy came and took them to his room (G1): "If not the boy but the little girl had come along looking for sweets, where would the sweets be?"—in L1. The children answered only 4 of 66 questions (6%) correctly, which is clearly below chance. The common error—as predicted if children engage in basic conditional reasoning and use the default assumption that each character takes sweets to his or her room—was to say that sweets would have ended up in the C2 character's room, Location G2 (39 of 66 questions = 59%; 64% of these children had answered with G2 in Condition 3 too). The children answered 10 of 66 questions (15%) with the actual location (G1: realist error) and 13 questions (20%) with the bottom shelf (L2).

In comparison, children gave 40 correct answers to 66 subjunctive past questions (61%) when the C2 character could have reached the sweets (Condition 3). This is not surprising if we assume that they applied basic conditional reasoning with a default assumption that sweets tend to end up in the respective character's room. When we asked, "But what if not the little girl but the tall boy (character C1/2) had come along looking for sweets . . .?" we expected most children to answer that the sweets would then be in the boy's room (Location G1) regardless of where mother had put them, and 73% in Condition 2 and 65% in Condition 4 gave the expected G1 answer.

To summarize, children responded correctly above chance levels in Conditions 2, 3, and 4 but below chance in Condition 1. This pattern of results conforms strongly to what we expected under the assumption that children solve problems by basic conditional reasoning (Table 1). To provide evidence of the participants' limited counterfactual reasoning skills, despite their knowledge of how the relevant transformations work, we compared the answers to subjunctive past questions, for example in Condition 1 with the answers to the corresponding indicative future questions, in this case in Condition 2. All four comparisons were highly significantly different (Wilcoxon signed ranks test: Z scores = −3.7 to −5.1; Cohen's ds = 0.83 to 2.81). It seems that the children generally understood the constraint on the girl (which we tested by indicative future, control, and memory questions), but were unable to create the correct counterfactual assumptions to infer that if C2 had come she would not be able to retrieve the sweets from L1.

Discussion

Experiment 1 demonstrates two clear effects. One of these is the replication of the difference between the number of correct answers on indicative future questions and on subjunctive past questions also found in studies by Perner et al. (2004), Riggs and Peterson (2000), Riggs et al. (1998), and Robinson and Beck (2000, Study 1). The other clear effect is that performance on the subjunctive past questions can be very different within the same story world. Children give mostly correct answers if they can derive them by basic conditional reasoning from preferred default assumptions.

In Condition 1 (top shelf, boy comes, takes sweets: If the little girl had come . . .?), the preferred default assumption leads to a wrong answer (girl's room). To get it right, children have to consider where mother had actually put the sweets. In other words, they have to construct a possible world that is maximally similar to the actual world, one that takes account of where the sweets had actually been put. Most children in Experiment 1 failed to do this, in apparent violation of Lewis's (1973) "nearest possible world" criterion.

Experiment 2

The results of Experiment 1 showed that most children younger than 6 did not use counterfactual reasoning but used basic conditional reasoning aided by background assumptions suitable for three but not all four conditions. One worry, however, is that children capable of counterfactual reasoning might have been trapped into unthinkingly using the simplified rule that the sweets end up in the searching character's room because this is the case in three of four event sequences. This is due to an asymmetry in the structure of the story worlds of Experiment 1 (see Figure 1). There are three event sequences in which the item is transferred to the protagonist's room (Locations G1 and G2) but just one event sequence in which the item stays in its initial location (Location L1), and this condition caused children-specific difficulties when we asked them counterfactually in Experiment 1. To eliminate any possibility that children might perform badly because the one condition was an exception, we modified the structure of the story worlds for Experiment 2 so that it was symmetrical. Thus, the structure of Figure 1 changed so that the line labeled C1/2 connecting L2 with G1 now also becomes self-reflective on L2; for example, the boy is no longer able to reach the sweets when they are at the bottom shelf, and therefore the sweets stay at L2. Because he can reach only L1, the C1/2 character becomes a C1 character.

If children's basic conditional reasoning and their preferred background assumptions led to the many errors in Condition 1 of Experiment 1 (where the counterfactual character could not reach the sweets), then in this experiment, children should commit most of their errors in Conditions 1 and 4. However, if children reasoned counterfactually in Experiment 1 but were misled by the fact that the sweets ended up in the character's room in three of four event sequences, then their errors in Experiment 2 should be equally distributed over the four conditions because now the sweets remain on the shelves and are brought to the characters' rooms an equal number of times.

There is a further reason for running this experiment. Children's problems with Condition 1 in Experiment 1 indicated that they apparently disregarded the first transformation (where mother put the sweets) when asked a subjunctive past question about the second transformation (if the little girl had come). This might have happened for different reasons. Children may simply have had difficulty in remembering where mother had put the sweets. Although we could show in Experiment 1 that children had few problems answering indicative future, memory, and control questions—implying that they knew the rules of the story world—it might be that they were unable to retrieve this information when we asked the subjunctive past question. Conversely, children may simply have failed to look further into the past than the counterfactual assumption led them to do. For instance, one can imagine that children, when asked what would have happened if the girl instead of the boy had come, would focus on this point in the story and the ensuing consequences of this counterfactual assumption, and ignore the facts earlier in the story, that is, whether the sweets had been on the top or the bottom shelf. A third possibility is that children did not understand that a subjunctive past question requires them to think of the actual events in the story world to arrive at a correct answer. If the first or second factor was the reason that prevented children from reasoning counterfactually, then making the earlier transformation (mother puts sweets into L1 or L2) counterfactual should solve their problems. So, for example, when we ask "But what if sweets had been on the bottom instead of the top shelf?" children need not look further into the past; moreover, the current location of the sweets reminds them of who had come to collect the sweets. However, if the third factor was the reason for giving the wrong answer, then the children should now have problems with Conditions 1 and 4 even when the first transformation is taken counterfactually. To test this, we introduced subjunctive past questions about the first transformation, where mother had put the sweets.

Method

Participants. Thirty-two children (19 boys, 13 girls) from two different preschools and nursery schools in Upper Austria, between the age of 5;0 and 6;5, participated in this study. They had a mean age of 5;10 with a standard deviation of 4 months. All participants were monolingual German speakers and came from working- and middle-class backgrounds. For the later analysis, the overall sample was split into two age groups. The 15 younger children were between the ages of 5;0 and 5;9 ($M = 5;6$, $SD = 0;2$), and the 17 children in the older age group were between 5;10 and 6;5 ($M = 6;1$, $SD = 0;2$).

Materials. We used the same materials as in Experiment 1, except that the dwarf story contained only the stone hut, not the wooden hut.

Design. We tested all children in one 20-min session during which we presented both story worlds (sweets story and dwarf story) and asked children eight control questions per story world. We used the same seven as in Experiment 1, with an additional question: "Why is the boy unable to take the sweets from the bottom shelf?" We gave each child four event sequences, two per story world, and we asked two test questions per sequence: an indicative future question (the same as in Experiment 1) and a subjunctive past question about either the first ("What if sweets had not been at L1 but at L2?") or the second transformation ("What if not C1 but C2 had come?"). Thus, each child answered four subjunctive past questions, two in which the location was the counterfactual element (for one story world the character could have reached the item, and for the other story world the character could not), and two in which the character was the counterfactual element (for one story world the character could have reached the item, and for the other story world the character could not). We used a Latin square design to control for variation.

Procedure. The procedure was basically the same as in Experiment 1, save for two modifications. In the sweets story, the tall boy had broken his leg and could not kneel down to reach the sweets on the bottom shelf. In the dwarf story, there was only one hut, the stone one whose door the dwarf can open to collect nuts. The squirrel cannot open the door of the stone hut but can climb up the tree to get to the nuts, whereas the dwarf is overweight and is unable to climb the tree. All nuts are *either* in the stone hut *or* on the tree.

Results

Control and memory questions. Children's performance in the control and memory questions of the sweets story and the dwarf story was excellent and practically identical for both story worlds, 98.4% versus 99.2%.

Indicative future questions. Children's performance on the indicative future questions was very good and did not differ significantly between the two story worlds (sweets story: 100% correct; dwarf story: 91% correct), Wilcoxon signed ranks test: $Z(N = 32) = -1.9$, $p = .06$, Cohen's $d = 0.35$. Two children made one mistake out of four questions, whereas 2 children made two mistakes; thus, overall, children answered almost 96% of the questions (122 of 128) correctly. Children did not perform significantly differently on indicative future questions, where the character is or is not able to reach the item, Wilcoxon signed ranks test: $Z(N = 32) = 0.0$, $p = 1.0$. Children seemed to understand that in some scenarios, the item stays where it is; only the youngest age group in Experiment 1 had problems with the indicative future questions where the item stayed in its location.

Subjunctive past questions. Children gave 59% correct answers to the subjunctive past questions in the sweets story and 75% in the dwarf story, Wilcoxon signed ranks test: $Z(N = 32) = -1.8$, $p = .08$, Cohen's $d = 0.31$. The Wilcoxon signed rank test showed a highly significant difference between answers to indicative future (96% correct) and to subjunctive past questions (63%), $Z(N = 32) = -4.5$, $p < .01$, Cohen's $d = 1.41$. Improvement on subjunctive past questions with age from 63% to 71%

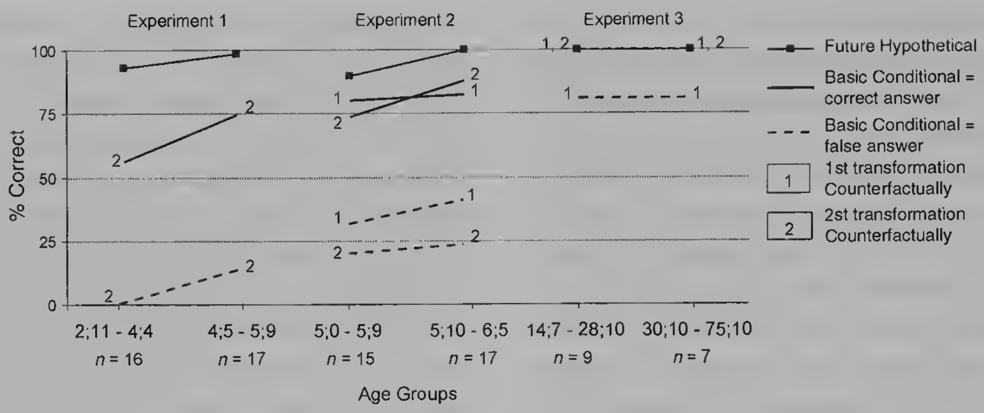

Figure 3. Percentage of correct answers to counterfactual questions depending on age.

correct was minimal and not significant, Mann–Whitney test: $U(n_1 = 15, n_2 = 17) = 103$, $p = .32$, Cohen's $d = 0.32$.

Figure 3 shows that Experiment 2 replicates the results of Experiment 1 rather closely: When the second transformation (searching character) is taken counterfactually, children do significantly worse when the character would not have reached the item (21.9% correct; dashed line, Conditions 1 and 4) than when he or she would have reached it (81.3% correct; solid line, Conditions 2 and 3), Wilcoxon signed ranks test: $Z(N = 32) = -4.2$, $p < .01$, Cohen's $d = 1.06$. There were no significant differences between Conditions 1 and 4, Mann–Whitney test: $U(n_1 = 16, n_2 = 16) = 104$, $p = .21$, Cohen's $d = 0.47$; or Conditions 2 and 3, Mann–Whitney test: $U(n_1 = 16, n_2 = 16) = 128$, $p = 1.0$. Thus, children's errors in Condition 1 of Experiment 1 did not result simply from the fact that it was the only condition in which the protagonist cannot reach the item.

The novel part of Experiment 2 was that we also asked children subjunctive past questions that altered the first transformation (where mother put sweets). Response patterns were similar (see Figure 3) and not significantly different from performance on the second transformation, Wilcoxon signed ranks test for first and second transformations: Conditions 1 and 4: $Z(N = 32) = -1.3$, $p = .20$, Cohen's $d = 0.35$; Conditions 2 and 3: $Z(N = 32) = 0.0$, $p = 1.0$. Children did significantly worse when the item would have stayed at its initial location (37.5% correct, dashed line, Conditions 1 and 4) than when it would have ended up in the character's goal location (81.3% correct, solid line, Conditions 2 and 3), Wilcoxon signed ranks test: $Z(N = 32) = -3.3$, $p < .01$, Cohen's $d = 0.71$. Neither Conditions 1 and 4, Mann–Whitney test: $U(n_1 = 16, n_2 = 16) = 96$, $p = .08$, Cohen's $d = 0.68$; nor Conditions 2 and 3, Mann–Whitney test: $U(n_1 = 16, n_2 = 16) = 120$, $p = .63$; Cohen's $d = 0.17$, showed a significant difference between the number of correct answers for the first or second transformation.

The pattern of answers on our subjunctive past questions allowed us to classify children according to the reasoning strategy that would result in the observed pattern. Table 2 shows the response patterns expected for counterfactual and basic conditional reasoning strategies. As children did not receive all eight conditions but only two for each transformation, the table shows which combination of conditions we gave to one group (a) and to the other group (b).

We classified children as *counterfactual reasoners* (CF) if they showed the counterfactual reasoning pattern on all four conditions (2 children) or on at least three conditions (4 children, allowing one lapse of attention). Four older (23%) and 2 younger (13%) children showed a counterfactual reasoning strategy. *Basic conditional reasoners* (BC) were those who showed the basic conditional reasoning strategy on all four (11 children) or at least three conditions (1 child), which applied to 6 older (35%) and 6 younger (40%) children. The binomial probability for inclusion in the CF group is as high as for the BC group: .02. An additional 4 children, 2 older (12%) and 2 younger (13%), showed a particular kind of incomplete basic conditional reasoning pattern, which resulted when they switched the person who came to search for the sweets (*searcher switchers* [SS]) when the location was counterfactually altered. For example, if the sweets are at L2, the C2 character comes searching for sweets, they end up in C2's room, and we ask children, "Where would the sweets be, if they had not been at L2 but at L1?" children pointed to C1's room. Although this pattern is technically BC (with one very specific lapse, which has a probability of .01), we kept it separate because, as we will see, we found the same pattern among some adults who otherwise

Table 2

Expected Answers for Each Reasoning Strategy in the Eight Conditions of Experiment 2

Condition	Actual events			CF change First transf.	Reasoning strategy		CF change Second transf.	Reasoning strategy	
	First transf.	Second transf.	End state		CF	BC		CF	BC
1	L1	C1	G1 a	L1 → L2	L2	G1 b	C1 → C2	L1	G2
2	L1	C2	L1 a	L1 → L2	G2	G2 b	C2 → C1	G1	G1
3	L2	C1	L2 b	L2 → L1	G1	G1 a	C1 → C2	G2	G2
4	L2	C2	G2 b	L2 → L1	L1	G2 a	C2 → C1	L2	G1

Note. "x → y" indicates that the real event x was replaced by the counterfactually assumed event y, that is, "if not x but y had happened." Transf. = transformation; CF = counterfactual; BC = basic conditional; L1 = sweet is on the top shelf/nut falls into the stone hut; L2 = sweet is on the bottom shelf/nut is on the nut-tree; C1 = boy/dwarf comes along; C2 = girl/squirrel comes along; G1 = boy's room/dwarf village; G2 = girl's room/squirrel's nest.

showed only counterfactual patterns. There were 3 children, 2 older (12%) and 1 younger (7%), whose pattern could be equally correctly classified as counterfactual or basic conditional reasoning (with one lapse of attention, CF/BC, with a probability of .008). Finally, the responses of 7 children, 3 older (18%) and 4 younger (27%), did not fit any of these response patterns, and we classified them as *nonsystematic.*

Discussion

We replicated the findings that children were much better at answering indicative future questions than subjunctive past questions in Experiment 2. There is clear evidence that children find future hypothetical reasoning much easier than counterfactual reasoning. Another aim of this experiment was to exclude the possibility that children's errors in Condition 1 of Experiment 1 occurred because it was the only condition in which the little girl could not have retrieved the sweets from the top shelf. The second experiment reveals that this was not the case. Despite balanced numbers, children still had problems in the conditions (1 and 4) in which basic conditional reasoning leads to a different answer than counterfactual reasoning does.

We also wanted to test alternative reasons for why children had problems in Conditions 1 and 4, specifically, difficulty in remembering the original location of the item and not looking farther into the past than the counterfactual assumption takes them. If these alternative accounts applied, then children should have found it easier to draw correct conclusions when we made the first transformation counterfactual than when the second was counterfactual. However, this was not the case. Children most likely used basic conditional reasoning rather than counterfactual reasoning.

This conclusion is underlined by the fact that, similar to the results of Experiment 1, at most 3 of the younger and 6 of the older children followed a consistent counterfactual reasoning strategy (also counting the CF/BC patterns as counterfactual) when answering subjunctive past questions, whereas 8 of the younger and 8 of the older children tended to display basic conditional reasoning (also counting the SS group, which showed a one-lapse basic conditional reasoning pattern).

Experiment 3

In particular, the results of the last experiment indicated that even at 6 years, few children, at best 35% (if the ambiguous CF/BC pattern is counted as CF), showed evidence of counterfactual reasoning. We wondered whether adults might be less than perfect on our problems, so in this experiment, we told the stories of Experiment 2 to a group of adults.

Method

Participants. Sixteen adults (7 men, 9 women) from ages 14;7 to 75;10 participated in this study. The youngest attended secondary school, 9 were university students enrolled in different fields of study, and the remaining 6 were middle-class employees. They had a mean age of 34;6 with a standard deviation of 16;3.

Procedure. The procedure was exactly the same as in Experiment 2.

Results and Discussion

The adults answered all control, memory, and indicative future questions correctly. Moreover, as Figure 3 shows, they also answered all subjunctive past questions correctly with one exception. When the first transformation (where mother put the sweets) was taken counterfactually, they gave only 81% correct answers, because 6 people showed the SS pattern we described for the small group of children in Experiment 2. When the object was counterfactually assumed to have been in a location where the actual character could not reach it, the participants assumed the character who could reach there would eventually come and fetch it.

At first blush, this appears to be a default assumption that 4 children also tended to make. However, unlike the 4 children, adults explained that they did not only reason about the fact that, for example, the girl cannot reach the sweets on the top shelf and thus sweets would have stayed there, but they continued to reason that at some later time the boy would come and take the sweets into his room. From these explicit explanations, it seems clear that adults did not engage in basic conditional reasoning that ignored the actual events. Another fact in favor of adults' counterfactual reasoning is that none of them showed the 4 children's tendency to use basic conditional reasoning when the second transfer was taken counterfactually.

As we did not elicit explanations from children about their answers, we cannot tell whether they did or did not follow the same strategy as adults. However, the 4 children also answered with the character's goal locations when the second transformation was counterfactually changed, which adults did not do, so the more parsimonious explanation is that the children showing the SS pattern took a basic conditional approach with the default assumption that the characters tend to bring the goods to their room. This can account for their answer patterns in both cases, when the first and the second transformations were taken counterfactually.

General Discussion

The principal aim of these studies was to get a clearer picture of children's ability to reason counterfactually by controlling for the distinction between counterfactual and other conditional reasoning strategies. With this distinction, we also hoped to shed light on the discrepancy between previous studies' claims about the onset of counterfactual reasoning.

In short, our explanation for this discrepancy is that previous research did not control for children's use of basic conditional reasoning strategies to answer subjunctive questions about the past. Counterfactual problems seem easy if one can correctly answer them with purely conditional reasoning (e.g., at 3 years, Harris et al., 1996; or 4 years, Riggs et al., 1998). They become very difficult when basic conditional reasoning with plausible default assumptions produces different answers than proper counterfactual reasoning would produce, as this research shows. Indications of that difficulty are also visible in children's understanding of counterfactual emotions like regret or relief (Amsel & Smalley, 2000; Amsel et al., 2003). To assess whether children reason counterfactually by following the ''nearest possible world'' constraint of Lewis (1973), we used counterfactual problems for which basic conditional reasoning would not produce correct answers. These problems required children and adults to think of what has actually happened and constrain the necessary assumptions for conditional reasoning to the actual events as far as logically possible (known as the nearest possible world). Results show that children, but not adults, tend to follow default assumptions unconstrained by actual events and governed by cognitive availability.

There are, however, competing explanations for results showing discrepancies in the age of onset of counterfactual reasoning. One claim is that children are more likely to engage in counterfactual thinking when the outcome is unwanted or negative (German, 1999; Guttentag & Ferrell, 2004; Roese, 1997). This factor could have contributed to our findings, as children had the hardest time with conditions in which a character reached the desired object, whereas they had an easier time with conditions in which the character failed to reach the desired object (negative outcomes supposedly stimulate counterfactual reasoning). However, as we discussed in the Introduction, many earlier studies found that negative outcomes had only minor effects on counterfactual reasoning (Amsel & Smalley, 2000; Amsel et al., 2003) or no advantage at all (Harris, 2000; Kavanaugh & Harris, 2000), so it is unlikely that the massive difference we found in the present study could be due to this possible but minor effect.

Another possible explanation for children's problems with subjunctive past questions is that they have difficulty in inhibiting their strong initial responses based on the current reality (Riggs et al., 1998). Beck et al. (2009) found that inhibitory control predicted children's performance on the counterfactual reasoning tasks; in contrast, Robinson and Beck (2000) questioned whether inhibition is a satisfactory explanation, as in many counterfactual reasoning tasks the only error children can plausibly make is to choose the current state of affairs. So, it is unclear whether children do in fact fail to inhibit reality or whether they fail to construct a counterfactual alternative. Robinson and Beck reasoned further that if children do tend to get trapped in current reality, then it should be easier for them to think of a counterfactual alternative to a *past* reality than to a *current* reality. Children in their study did equally well in both conditions, suggesting that they do not get trapped in current reality. In a similar vein, Riggs et al. (1998) pointed out that inhibitory control cannot account for the difference in performance between counterfactual and future hypothetical reasoning because otherwise children should have problems inhibiting reality in most future hypothetical reasoning tasks as well, as the hypothetically assumed antecedent often differs from known reality, but in fact they do not experience difficulty with future hypotheticals. In any case, in our stories children hardly suffered from realist errors. Their typical errors consisted of answering with another counterfactual location, not with the object's current location. Hence, our results are clearly not the result of weak executive control in inhibiting realist answers.

Working memory limitations, in contrast, might provide a more convincing account for children's failure to engage in counterfactual reasoning. One could argue that children might understand that they should construct a nearest possible world by taking actual events into account but fail to do so because they lack the memory capacity to remember the actual event, construct the counterfactual scenario, and integrate that counterfactual with the actual event. Beck et al. (2009) tested whether working memory capacity can predict 4-year-old children's success on counterfactual reasoning tasks. However, the relation between working memory tasks (Counting and Labeling; Noisy Book) and counterfactual reasoning tasks (causal chains by German & Nichols, 2003; unexpected transfer by Riggs et al., 1998, and false syllogisms) was at most .28. Thus, an overly taxed working memory cannot exclusively—if at all—explain children's difficulties with counterfactual reasoning tasks. Working memory might explain younger children's difficulty with subjunctive past questions when holding two models simultaneously active, but it cannot explain the older children's problems.

Thus, our central finding is that children only gain the ability to reason counterfactually as late as 5 or 6 years. This late onset might also explain why Amsel et al. (2003; Amsel & Smalley, 2000) as well as Guttentag and Ferrell (2004) report such late understanding of counterfactual emotions. We designed our tasks so that in the critical conditions children could only give correct answers if they naturally adhered to the "nearest possible world" constraint, that is, if they related their conditional reasoning to actual events. This makes it similar to showing counterfactual emotions, except that the direction of the relation is reversed. For instance, regret can be felt only if one compares what one actually received with what one could have received if one had chosen or acted differently. If children up to 6 years or older do not spontaneously compare assumed conditions with actual conditions, they would perform badly on our tasks and on the counterfactual emotions tasks.

On some other counterfactual tasks (defined by the use of past subjunctive questions), however, much younger children before the age of 5 years perform practically at ceiling (Harris et al., 1996; Riggs et al., 1998). We can explain this by assuming that in these tasks, basic conditional reasoning leads to the same "correct" answers as counterfactual reasoning.

Our suggestion that children give correct answers based on basic conditional reasoning opens up a new venue of explanation. It is related to the idea that with each additional step, it becomes less likely that all of the required default assumptions match the "nearest possible world" criterion. For instance, in the scenarios by Harris et al. (1996), the stipulated antecedent "If Carol had taken her shoes off, would the floor be dirty?" triggers fairly directly the relevant knowledge that without shoes, the floors stay clean. In the scenario Riggs et al. (1998, Experiment 1) used, the reasoning is not so straightforward: "If there had been no fire, where would Peter be?" triggers knowledge that without a fire, firemen could be anywhere. However, the story provides children with two possible locations, namely, the ones mentioned in conjunction with Peter: home or post office. With the reality bias diminishing, children will increasingly bring more sophisticated assumptions to bear, for example, that people are more likely to be at home than at the burning post office. Such knowledge would increase "home" responses even though children are still applying basic conditional reasoning.

The findings by Amsel, Trionfi, and Campbell (2005) seem to support this assumption. They compared 6-year-olds, 10-year-olds, and college students' performances on two conditions: (a) *pretend* that in a make-believe world dogs meow and (b) *imagine* what the real world would be like if dogs meowed. Both conditions presented a minor premise, "Rover is a dog," followed by a question, "Does Rover meow?" The main finding was that 6- and 10-year-old children performed correctly (saying *yes*) more frequently in the pretend condition than in the imagine condition, whereas this difference vanished among college students. The crucial difference is that in the pretend condition, one does not assume that dogs meow in the real world, whereas in the imagine condition one must assume this, which obviously makes the imagine condition a counterfactual, as dogs do not meow in reality. It is well known that children perform better on counterfactual syllogism tasks when the counterfactual premise is framed as pretend (Dias & Harris, 1988; Richards & Sanderson, 1999). This is especially interesting when we consider that the children in our studies found it easier to make background assumptions that were not constrained by reality than to reason with assumptions that were constrained by reality.

The assumption that children use basic conditional reasoning in counterfactual tasks is compatible with a study by Robinson, Rowley, Beck, Carroll, and Apperly (2006), who used a setup in which a mouse went down a slide that split halfway down into a spotted or a striped slide. In one condition, researchers asked the questions when it was still unknown which way the mouse would go (physical possibilities), whereas in the other condition the mouse had already gone into one branch but the child had no knowledge which branch that was (epistemic possibilities). To do the task right, children had to put out two mats to make sure that the mouse that came down a slide did not get hurt. A total of 87% of 6-year-olds put both mats out in the physical-possibilities case, but only 43% did so in the epistemic-possibilities case. The epistemic case shares with counterfactual reasoning the need to construct alternative models for an existing state of the world, an ability that seems to emerge around 6 years of age.

Conclusion

We found a large discrepancy in correct answers to past subjunctive questions under two different conditions. When basic conditional reasoning yielded the correct answer, children did much better than when they had to observe the "nearest possible world" constraint—that is, when they had to demonstrate proper counterfactual reasoning. With this discovery and known observations from the literature, we can describe children's progress on counterfactual reasoning problems that use past subjunctive questions as follows. At 3 years, children still have a noticeable reality bias, but this bias practically disappears by 4.5 years. Children at this age are, however, still not perfect on counterfactual problems because they use basic conditional reasoning instead of counterfactual reasoning. The likelihood of a correct answer depends on what general knowledge they can bring to bear on the conditional antecedent presented in the question and how directly it indicates the correct answer, that is, whether it leads specifically to the correct answer or only contains that answer in a set of options. By 5 or 6 years, some children start to reason counterfactually. They do not leave their reasoning exposed to the vacillations of cognitive accessibility; instead, they understand that it must follow the givens of the actual events as closely as possible (the nearest possible world). Adults' mastery is close to perfection, at least on our kinds of task. However, one could argue that the few older children who give "counterfactual" answers, instead of using counterfactual reasoning, might have used basic conditional reasoning together with expedient background assumptions—in our study, that the sweets were stored in the top or bottom shelves as a result of where the sweets had actually been stored. This remains a possibility, which future research should clarify. We also leave it to future research to plot the developmental improvements from 6 years to adulthood.

Sensing the Coherence of Biology in Contrast to Psychology: Young Children's Use of Causal Relations to Distinguish Two Foundational Domains

Jane E. Erickson, Frank C. Keil, and Kristi L. Lockhart
Yale University

To what extent do children understand that biological processes fall into 1 coherent domain unified by distinct causal principles? In Experiments 1 and 2 ($N = 125$) kindergartners are given triads of biological and psychological processes and asked to identify which 2 members of the triad belong together. Results show that 5-year-olds correctly cluster biological processes and separate them from psychological ones. Experiments 3 and 4 ($N = 64$) examine whether or not children make this distinction because they understand that biological and psychological processes operate according to fundamentally different causal mechanisms. The results suggest that 5-year-olds do possess this understanding, and furthermore, they have intuitions about the nature of these different mechanisms.

Young children seem to have a clear sense that there are fundamentally different kinds of things in the world, or ontological categories, and they distinguish them by using different causal-explanatory frameworks (Carey, 1985; Keil, 1989; Murphy & Medin, 1985; Wellman & Gelman, 1992, 1998). Many questions remain, however, about the nature of these causal frameworks and how they guide acquisition and use of knowledge. Related questions ask how these frameworks develop into more sophisticated domain-specific causal ''theories'' possessed by lay adults. Here we explore aspects of the internal structure of such frameworks and consider the implications for models of conceptual development.

Three sorts of causal-explanatory frameworks have dominated much of the discussion on domain-specific causal principles—those fundamental to the domains of physics, psychology, and biology. The discussion revolves around the process through which children become aware of which entities belong in each of these domains and the extent to which the assignment of entities to domains is based on knowledge of deeper causal relations. Even preverbal infants consistently differentiate between animate and inanimate things and display some understanding of the causal principles driving the actions of entities within each of these domains (Baillargeon, 1994; Bertenthal, 1993; Bullock, 1985; Gelman, Durgin, & Kaufman, 1995; Poulin-Dubois & Shultz, 1990; Rakison & Poulin-Dubois, 2001; Rochat, Morgan, & Carpenter, 1997; Sommerville & Woodward, 2005; Spelke, Phillips, & Woodward, 1995; Surian, Caldi, & Sperber, 2007).

However, it remains less clear how an understanding of the fundamental principles underlying biological processes emerges in development. The animate–inanimate distinction may be a precursor to understanding the domain of living things, but this distinction can be easily approximated perceptually according to which objects move on their own, which objects engage in goal-directed actions, and which objects show other perceivable patterns of biological behavior or motion unique to living kinds. To proceed from an animate–inanimate distinction to an understanding of the living–nonliving distinction, one must group together entities that vary drastically on the perceptual level both statically and dynamically (plants and animals against nonliving natural kinds and artifacts). This requires

that one look past perceptual features to identify more fundamental characteristics of living things, such as physiological properties and processes they share in common, and the causal structures that explain these characteristics and behaviors (namely, that these entities are living and thus need to perform certain actions to maintain their survival in niches they typically inhabit).

One influential view claims that children do not have an understanding of biology and its underlying causal principles until late in childhood, and argues further that children first conceive of living things in a psychological, not biological, framework (Carey, 1985; Solomon, 2002; Solomon, Johnson, Zaitchik, & Carey, 1996). This view arises from the finding that children fail to group together plants with animals into one category (i.e., *living thing*) that guides their reasoning about biological parts and properties. Second, children reason about biological processes in terms of psychological states such as desires and beliefs. For example, when asked why various living things sleep or reproduce, children younger than 7 years old answer, ''Because they want to dream'' or ''Because they want to have babies,'' thereby making reference to desires and thus construing these processes as psychological, rather than biological, in nature. These sorts of studies seem to suggest that children do not have an understanding of biology—neither of what entities are alive nor an understanding of the causal mechanisms responsible for biological properties and processes. Instead, children's concept of *living thing* is akin to *animate thing* or an entity possessing mental states. All of the properties and behaviors of these entities are therefore supposedly understood to be the result of psychological, as opposed to biological, causal mechanisms.

Some researchers, however, argue that young children do possess a concept of *living thing* that includes both plants and animals while excluding nonliving things (Inagaki & Hatano, 2002; Keil, 1992, 1994; Waxman, Medin, & Ross, 2007). These researchers believe that children do have an understanding of some causal principles fundamental to the domain of biology, and furthermore, children understand that these principles differ from those in the physical and psychological domains.

Much of the debate revolves around induction projection tasks. In Carey's (1985) landmark series of studies young children projected biological properties based on psychological similarity to human beings, a pattern that was taken as showing that biology was not seen as distinct from psychology. Young children project a property, such as ''has a heart'' to dogs because they interpret hearts as supporting subjective well-being, something they see as a reasonable psychological state for a dog. They did not, however, seem to project ''has a heart'' to worms or other insects, a pattern that was explained on the grounds that such creatures are too psychologically dissimilar from humans. This pattern of projection, however, does not necessarily mean that children can only engage in psychological reasoning about biological properties. Projection experiments using a context/no-context manipulation find different results (Gutheil, Vera, & Keil, 1998; Inagaki & Hatano, 1996). For example, in one study's (Gutheil et al., 1998) biological context condition, children were told how the given property was biologically important to humans before being asked to project it onto other entities (e.g., ''This person eats because he needs food to live and grow. The food gives him energy to move. If he doesn't eat, he will die.''). In that context condition, both 4- and 5-year-olds properly extended this property to low-level organisms but not to nonliving things, unlike young children in Carey's studies or children in that study's no-context or social-context condition. These sorts of findings suggest that children do in fact have a concept of *living thing* as something separate from *animate* or *psychological thing*, but this concept needs to be made salient. In other words, psychology may be the default method of reasoning about the actions of most living things for young children, but a biological understanding may also be present and elicited in the right contexts.

The same message is emerging from cross-cultural studies, where certain cultures seem to provide contexts that early on make biological relations the default option in inductive reasoning tasks. Young children from more rural settings often show patterns of induction that seem to be based on biological principles (Medin & Waxman, 2007; Ross, Medin, Coley, & Atran, 2003). Indeed, it may be that urban and suburban contexts should be thought of as more atypical in that they reduce an emphasis on biological ways of construing the world, a pattern that converges with arguments that biological knowledge may have ''devolved'' in some developed areas of the West (Atran, Medin, & Ross, 2004).

More broadly, young children often seem to understand there are processes distinct to biological entities, and further, they see them as distinct from psychological ones. For example, children as young as 5 years seem to know that animals and plants, but not nonliving natural kinds and artifacts, grow in size over time (Inagaki & Hatano, 1996; Keil, 1983; Rosengren, Gelman, Kalish, & McCormick, 1991) and are capable of self-healing (Backscheider, Shatz, & Gelman, 1993; Inagaki, 2001; Inagaki & Hatano, 1996). Children also show different attribution patterns for biological and psychological processes across different entities (Coley, 1995; Jipson & Gelman, 2007), suggesting they do not treat these processes as one and the same.

In addition to studying which entities young children think are susceptible to biological processes, another way to discover whether or not they see a fundamental distinction between the biological and psychological domains is to look more closely at what children think are the causal mechanisms underlying biological phenomena. Are biological processes seen as being caused by mental states (psychology) or by physiological mechanisms (biology)? Preschoolers do seem to understand that parentage (biological factors) plays a greater role than friendship (social factors) in determining certain biological characteristics (Springer, 1992, 1996). Similarly 4- to 6-year-olds recognize that biological factors (e.g., eating and sleeping habits) play a greater role in one's susceptibility to illness than do social factors (e.g., lying; Inagaki, 1997). Preschoolers also rate explanations of contagions or contamination as better explanations than those of immanent justice for contracting an illness (Inagaki, 1997; Kalish, 1997; Siegel, 1988; Springer & Ruckel, 1992). Other studies have found that young children have a hard time conceiving of biological states (e.g., headaches, toe swelling) arising from psychological causes and that psychosomatic and psychogenic bodily reactions require a more sophisticated understanding seen only in adults (Notaro, Gelman, & Zimmerman, 2001; Shulz, Bonawitz, & Griffiths, 2007). Although in other cultural contexts young children may favor social and psychological explanations over biological ones (Astuti, Solomon, & Carey, 2004), it is clear that young children do have access to biological modes of explanation and they often can link these appropriately to the set of living things.

Because intention plays a large causal role in understanding psychological mechanisms, other studies have looked at whether or not children understand that mental processes are under voluntary control while bodily processes are not. A number of researchers (Inagaki, 1997; Inagaki & Hatano, 1993; Smith, 1978) have found that children 4- and 5-year-olds can correctly identify certain processes as voluntary (e.g., chewing) or involuntary (e.g., feeling pain). Similarly, other studies (Inagaki & Hatano, 1993; Lockhart, Chang, & Story, 2002; Lockhart, Nakashima, Inagaki, & Keil, 2008; Miller & Bartsch, 1997) have shown that children think physical characteristics are more difficult to change than psychological ones, in addition to each being modifiable through different means (mental effort for psychological characteristics and physical practice for physical characteristics). These results suggest that children are able to differentiate between bodily and mental processes, while also having some understanding that the latter are under psychological control whereas the former are not.

There are also specific indications that young children may be relying on causal intuitions when they contrast biological and psychological process. One series of studies has looked at children's understanding of trait origins and the ways in which different kinds of interventions might be connected to psychological and biological phenomena (Lockhart, Aw, & Essig, 2004; Lockhart, Nakashima, & Inagaki, 2004; Lockhart et al., 2008; Nakashima, Lockhart, & Inagaki, 2003). For example, Lockhart et al. (2004) showed that children as young as 5 years of age linked the origins of psychological traits more to effort and instruction and the origins of biological traits more to inborn factors. These beliefs about differential origin accounts were then mirrored by beliefs about interventions, one of the hallmark ways of assessing causal reasoning. When asked what sorts of interventions would be most effective in changing traits, children at all ages thought that taking medicine or simply waiting for maturation to take its course would be more effective in changing physical traits than psychological ones. In contrast, interventions involving effort or instruction were seen as more influential for changing psychological traits.

All of the above studies suggest that by the time children are in kindergarten, they understand that animals and plants are similar in comparison with nonliving things by virtue of having capacities such as reproduction, growth, self-healing, susceptibility to illness, and so on. However, the majority of these studies tended to either test only one biological phenomenon at a time or simply looked to see if children grouped plants with animals, as against nonliving things, when making inductive inferences. The extent to which children's understanding of the biological domain is systematic and coherent remains unclear. Do kindergarten-aged children see some degree of unification and clustering to biological processes, rather than reacting to isolated instances and comparing them on a case-by-case basis? To what extent do young children see these mechanisms and phenomena as hanging together in a larger system unified by causal principles that are different from those operating in other domains?

The following studies address these questions by giving children processes that span the entire domains of biology and psychology, and asking whether or not children classify these processes as belonging to fundamentally different categories distinguished by their underlying causal mechanisms. Experiments 1 and 2 present participants with triads of both human and animal biological and psychological processes and ask which two members of the triad belong together, allowing us to look at the clustering of processes within both domains. Experiments 3 and 4 further examine whether this clustering is based on simple associations or stems from a deeper understanding of the causal principles distinct to each domain. We test participants' understanding of these causal principles by having them reason about interventions, a method often used to assess knowledge of causal relations in various domains (Hagmayer, Sloman, Lagnado, & Waldmann, 2007; Kushnir & Gopnik, 2005; Kushnir, Gopnik, Schulz, & Danks, 2003; Sommerville, 2007; Steyvers, Tenenbaum, Wagenmakers, & Blum, 2003; Woodward, 2003). Indeed, judgments about interventions have often been claimed to be at the heart of identifying underlying causal relations (Woodward, 2003).

Based on the research just reviewed we hypothesize that children will succeed in making a general domain distinction among an array of biological and psychological phenomena by the time they are in kindergarten, thus displaying an understanding of biology and psychology as two fundamentally separate, but internally coherent, domains with different underlying causal structures. We further hypothesize that children may display this competence without explicitly understanding the detailed mechanisms related to those properties. This second prediction follows from studies showing that even adults often have strikingly incomplete understandings of mechanisms in various domains (Rozenblit & Keil, 2002) and that children can cluster phenomena in broad domains such as physical mechanics and social behavior while being unable to explain these phenomena (Keil, Stein, Webb, Billings, & Rozenblit, 2008).

Experiment 1a

Method

Participants. Participants were 24 kindergartners (M = 5 years 9 months) and 24 undergraduates with approximately an equal number of males and females in each age group. The children were recruited from local elementary schools and were predominantly from a White upper-middle-class background. The parents of all children gave written consent and each child agreed to participate. The kindergartners were tested in a quiet room at their school and were compensated with a sticker and a certificate. The undergraduates were recruited from university sign-up sheets and received minimal compensation (a candy bar) for their participation.

Materials. We used the deference method (Danovitch & Keil, 2004; Keil et al., 2008; Lutz & Keil, 2002) to discover the extent to which kindergartners differentiate biological from psychological processes. This method has been successful in discovering how children understand knowledge clusters within different domains. By investigating to whom children defer about a domain-specific process we can gain a greater understanding of what comprises a coherent domain of knowledge for young children. For example, Lutz and Keil (2002) found that preschoolers appropriately deferred to either a mechanical or a biological expert when given phenomena within the two domains, suggesting they are able to differentiate between biological and physical processes. Additionally, Danovitch and Keil (2004) demonstrated that children come to prefer consulting experts with knowledge of underlying scientific principles, as opposed to experts of trivia knowledge, and Keil et al. (2008) showed that even kindergarteners are sensitive to underlying causal structures in many broad domains corresponding roughly to the natural and social sciences. These results suggest that children understand there are different domains of knowledge structured according to deep causal principles. Moreover, children expect that experts who have knowledge of those principles should also have an understanding of a very broad domain of phenomena arising from them. That is, even young children realize that knowledge of certain key causal relations in a domain provide a person with a generative capacity to understand a potentially unlimited range of domain-specific phenomena that are governed by those principles.

In the present study we used the deference task to assess participants' understanding of biology and psychology as two distinct domains. Participants were given 16 questions phrased in the following way: "If I want to know about X, should I ask someone who knows about Y or someone who knows about Z?" In half of the questions, Y was a biological process and Z was a psychological process; this order was reversed for the remaining half. For example, a biological question would look like the following: ''If I want to know why people need to drink lots of water (biological), should I ask someone who knows why people get stuffy noses (biological), or someone who knows why people are bullies (psychological)?'' A psychology question would be phrased in the same manner but with a psychological process being questioned: ''If I want to know why people sometimes think out loud (psychological), should I ask someone who knows why people need sleep to grow taller (biological), or someone who knows why people like to learn new things (psychological)?''

We chose 24 biological and 24 psychological processes we thought spanned the full range of both domains. These processes were further divided into two subcategories within each domain: *health* and *illness* in biology and *cognitive* and *emotional* in psychology. The ''health'' subcategory in biology included items such as growth, general nutrition, benefits of exercise, and so on, whereas the ''illness'' subcategory included processes dealing with aging, bodily malfunction, sickness, and self-healing. In the ''cognitive'' subcategory of psychology, we included things such as learning, memory, reasoning, and problem solving, whereas the ''emotion'' subcategory included processes that focused more on personality traits, social relationships, emotions and motivation. We realize there may be more than one way to split up the domains of biology and psychology, but we chose these particular subcategories because they are both salient in the lives of young children (there are many everyday instances of each) and because they are often clearly contrasting areas in adult discussions of these domains. Thus, there are clearly distinct adult groups of experts on wellness, pathology, social psychology, and cognitive psychology.

We included items from two subcategories within each domain not only to ensure we chose a wide range of processes but also to ensure we could compare performance on within- and between-subcategory questions. Half of the questions included in this task were *within subcategory*, meaning that participants need only match processes within the same subcategory. For example, a psychology question asking about a cognitive process would have two answer options: a biological process and a psychological process from the same ''cognitive'' subcategory. The other half of the questions was *between subcategory*, requiring that participants abstract across the full domain in order to answer the question correctly. For example, a psychological between-subcategory question that asked about a cognitive process would have two answer options: a biological process and a psychological process from a different psychological subcategory (emotional). In this case, participants have to recognize how two very different processes (cognitive and emotional processes) are fundamentally similar to one another, and different from those in the domain of biology.

The between-subcategory questions are the strongest test of our hypothesis, namely, that kindergartners recognize a common domain across these two distinct subdomains. However, we chose to include the within-subcategory questions because, it is possible that kindergartners are not yet able to recognize the similarities among all biological processes, or all psychological processes, but are able to recognize similarities on a more local level—within a particular subcategory. For example, we think young children will notice that learning and memory are similar to one another (both cognitive activities) before they are able to grasp that learning and memory are similar to other psychological processes such as feeling scared or wanting to help others. We could find that participants are able to recognize the biology–psychology distinction on a local level when presented with processes that are similar within each domain. In other words, it is possible that kindergartners recognize that cognitive processes are similar to one another, and different from biological ones, but fail to understand that all psychological processes are fundamentally similar in that they share a common set of underlying causal principles related to one's mental life that are different from those at the core of biological phenomena.

Eight of the processes in each domain (four from each subcategory) were used as the target in question whereas the remaining 16 processes were included as answer options. A complete list of the stimuli can be found in Appendix A with an asterisk next to those processes that were used as questions.

The answer choice pairings were counterbalanced across two conditions so one group of participants saw a particular pairing with a biological question whereas the other group of participants saw the same pairing but with a psychological question. The same questions and answer pairings were used with all participants, but in different combinations between the two counterbalanced groups. This counterbalanced design ensured that neither of the answer options was inherently preferable to the other.

We were careful in constructing the question–answer pairings to eliminate the possibility that participants could use a simple heuristic to cluster processes within each domain. For example, although we incorporated anatomical terms into the psychology items, they were more frequent among the biology items. However, if a body part was mentioned in the biology target question, it was not mentioned in the corresponding biology answer option and vice versa. Furthermore, all of the items were subject to latent semantic analysis to make sure neither of the answer options was more statistically related to the target question than the other. Given a large and representative corpus of text, latent semantic analysis looks at all of the contexts in which a given word is or is not used to determine where each word in the English language stands in relation to all other words in terms of how often such words co-occur either directly or indirectly through joint co-occurrence with other words (Deerwester, Dumais, Landauer, Furnas, & Harshman, 1990; Landauer, 1998; Landauer, Foltz, & Laham, 1998). This method therefore helps determine how close words are to each other in a multidimensional, correlational space. For our particular stimuli, this method was used to verify that the set of words in each answer option was not any more related to the set of words in the question given the many other contexts in which these sets of words have appeared (both answer options were equally correlated with the question). Such computations can be made at the following Web site: http://lsa.colorado.edu/. It might well be the case that in typical use, there would be higher levels of correlation between words used in a common domain and that such correlations might be a cue to relatedness. Here, however, we controlled for such statistical relatedness to ask if children could still cluster processes by using a deeper conceptual understanding that went beyond merely noting patterns of co-occurrence among lexical items.

Adult participants were given the questions in a paper-and-pencil task. The kindergartners were asked the questions by an experimenter, each question being accompanied by a pictorial representation of each process for memory purposes. The pictures were all acquired from Clip Art and controlled for gender, age, number of people in each picture, and any other surface features children might use to make a decision. See Experiment 1b for confirmation that kindergartners could not rely on the pictures alone to perform this task successfully.

Procedure. Before beginning the experiment, kindergartners were given a training task to make sure they understood the deference method being used. They were first asked if they ever had a question about how things worked or why certain things happened. If they did not come up with something on their own, they were prompted by the experimenter with a question such as: ''Have you ever wondered why you need to eat vegetables?'' Once there was a question established, the experimenter inquired about who the child asked or would ask if they wanted to know the answer. The children were then instructed that in the following task they were going to be given questions and their job was to give the experimenter advice about who to ask in order to find the answer. They were told there would be two people the experimenter could pick from, and they should think really hard about which person the experimenter should ask as the two people ''know about different kinds of things.'' After children were given these instructions, they were presented with two crucial practice items—both of which they had to pass to continue on with the experiment. The first practice item was the following: ''If I want to know why it sometimes rains outside, should I ask someone who knows about the weather or someone who knows about sports?'' The second practice item was more difficult because the answer options were both topically similar to the question, thus requiring that children use their knowledge of domain-specific principles to answer the question: ''If I want to know how a TV works, should I ask someone who knows all about the parts inside of a TV or someone who knows all about cartoons on TV?'' All of the kindergartners passed both practice items.

After completing the training items, the experimenter then proceeded to the test items reminding children there were no right or wrong answers. As each question was asked, a sheet with three pictures was placed in front of the child—one picture for the question and one picture for each answer option. After the child chose one of the experts, the pictures were removed, new pictures laid before the participant, and another question was asked. Throughout the experiment, participants were randomly asked to repeat the question and answer options, and sometimes to explain their answers. No feedback was given to the participants during this time. This questioning was simply to make sure that participants were engaged in the task and were able to remember the question and each answer option. Adult participants completed this task on paper in a quiet room in our laboratory. They were given written instructions directing them to circle the best answer out of the two given.

Results and Discussion

Accuracy was computed as the average proportion of questions for which participants correctly matched processes within the two domains (biology with biology and psychology with psychology). No differences were found between the two groups that counterbalanced the question and answer pairings for the kindergartners ($M = .77$, $SD = .01$ vs. $M = .82$, $SD = .02$), $t(22) = .92$, $p = .37$, or adults ($M = .96$, $SD = .002$ vs. $M = .94$, $SD = .004$), $t(22) = .94$, $p = .36$, so we collapsed the scores within each age group for the remaining analyses. The results from Experiment 1, including a breakdown by domain (biology and psychology) and by type of question (within or between subcategory), are depicted in Figure 1.

Adults were used as a baseline to compare the performance of kindergartners. Both adults ($M = .95$, $SD = .053$), $t(23) = 41.40$, $p < .001$, and kindergartners ($M = .80$, $SD = .124$), $t(23) = 11.70$, $p < .001$, performed significantly above chance on the overall task, although adults performed better than kindergartners, $t(46) = 5.64$, $p < .001$. Performance was also assessed separately for the biology and psychology items. Kindergartners and adults performed significantly above chance on both the biology—kindergartners: ($M = .83$, $SD = .13$), $t(23) = 12.09$, $p < .001$; adults: ($M = .97$, $SD = .07$), $t(23) = 33.78$, $p < .001$—and psychology items—kindergartners: ($M = .77$, $SD = .21$), $t(23) = 6.39$, $p < .001$; adults: ($M = .94$, $SD = .072$), $t(23) = 29.70$, $p < .001$—with no differences found between the two domains—kindergartners: paired-$t(23) = 1.15$, $p = .26$; adults: paired-$t(23) = 1.63$, $p = .12$. Furthermore, all scores within each of the subcategories were significantly above chance for both groups of participants.

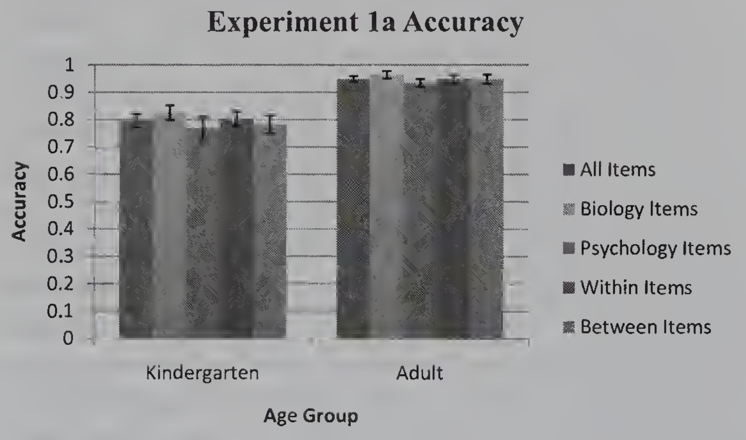

Figure 1. Experiment 1a accuracy scores for both kindergartners and adults. The overall accuracy is represented in the first bar for both age groups. The four remaining bars represent the accuracy broken down in two ways: by type of process (biological or psychological) and by type of question (within or between).

We further analyzed the within- and between-subcategory questions separately to see whether the children's success on the task was driven solely by their performance on within-subcategory questions. The kindergartners and adults performed significantly above chance on both the within- and between-subcategory items—kindergartners: ($M = .80$, $SD = .13$), $t(23) = 11.71$, $p < .001$, and ($M = .78$, $SD = .16$), $t(23) = 8.57$, $p < .001$, respectively; adults: ($M = .95$, $SD = .07$), $t(23) = 30.92$, $p < .001$, and ($M = .95$, $SD = .08$), $t(23) = 27.30$, $p < .001$, respectively—and performed equally well on both types of questions—kindergartners: paired-$t(23) = .68$, $p = .504$; adults: paired-$t(23) = .019$, $p = .99$.

These results suggest that kindergartners accurately distinguish biological from psychological processes. They performed equally well on the biology and psychology items, including consistent performance across each of the subcategories. Furthermore, their similar performance on the within- and between-subcategory items suggests that they have a robust understanding that all of the processes within each of these domains cluster with one another allowing the children to consistently classify them together.

Experiment 1b

The pictures used with the kindergartners in Experiment 1a were intended solely as memory aides and were chosen so as to offer no hints to the correct answer. However, we found while running the experiment that most of the kindergartners answered the questions by pointing at one of the two pictures representing the answer options. We decided to present a separate group of kindergarten participants with the same pictures, but this time without the verbal descriptions of the processes they represent. If kindergartners are finding superficial cues in the pictures to help them pair the correct answer option with the target in question, then they should perform equally well (and above chance) when presented with the pictures alone. If, however, the pictures are solely functioning as memory aides and do not give children any hints to the correct answers, then they should perform no better than chance (50% accuracy) on the task using only the pictures as their basis for judgment.

Method

Participants. Participants were 15 kindergartners (M = 5 years 9 months; 7 males, 8 females) who were recruited from local elementary schools and were predominantly from a White upper-middle-class background. The parents of all children gave written consent and each child agreed to participate. The kindergartners were tested in a quiet room at their school and were compensated with a sticker and a certificate.

Materials and procedure. In Experiment 1a, three pictures (representing three processes) were presented to kindergarten participants during each question. The first picture represented the target process in question, whereas the second two pictures represented the processes in each answer option. For example, three pictures accompanied the following item: "If I want to know why people need to drink lots of water, should I ask someone who knows why people get stuffy noses, or someone who knows why people are bullies?" The first picture depicted drinking lots of water, whereas the other two depicted stuffy noses and people being bullies.

These same picture triads were presented to participants in Experiment 1b but without the verbal descriptions of the processes they represent. These participants were instead asked which of two pictures "went with" or was "more similar to" the third target picture. A total of 32 picture triads (16 from each counterbalanced group in Experiment 1a) were presented to the participants.

Results

Accuracy was computed as the average proportion of questions for which participants matched pictures depicting processes within the same domain (biology with biology and psychology with psychology). Participants performed no better than chance on the triad task when only using the pictures as their basis for judgment ($M = .53$, $SD = .07$), $t(14) = 1.04$, $p = .13$. This remained true when the data were analyzed separately for the picture triads in each counterbalancing condition ($M = .51$, $SD = .106$), $t(14) = .34$, $p = .74$, and ($M = .55$, $SD = .08$), $t(14) = 2.15$, $p = .09$, respectively.

We can conclude from Experiment 1b that kindergartners could not have performed well in the first experiment if they only relied on the pictures to match various processes. This further demonstrates that kindergartner's success on the triad task in Experiment 1a results from a deeper understanding of biological and psychological processes as belonging to two distinct domains.

Discussion

Experiment 1 demonstrates that kindergartners appropriately cluster biological processes with one another while separating them from psychological ones. These results suggest that young children do sense the coherence among biological processes.

Although we chose a wide range of biological and psychological processes in Experiment 1, we were limited in that the biological referent was always a human being. In order to include the greatest range of processes in both domains, we expanded our items in Experiment 2 to also include a more diverse set of biological entities.

Experiment 2a

Method

Participants. Participants were 24 kindergartners (M = 5 years 10 months) and 24 undergraduates with approximately an equal number of males and females in each age group. The scores from two additional kindergartners were dropped, one for failing to complete the experiment and the other for failing the training task and always picking the second answer option for every question. The children were recruited from local elementary schools and were predominantly from a White upper-middle-class background. The parents of all children gave written consent and each child agreed to participate. The kindergartners were tested in a quiet room at their school and were compensated with a sticker and a certificate. The undergraduates were recruited from university sign-up sheets and received minimal compensation (a candy bar) for their participation.

Materials. We used the same deference task as in Experiment 1 but with two major changes. First, instead of focusing on human biology and psychology, we expanded our items to include a range of animals and, thus, a greater range of processes within each domain. Second, we eliminated the within-subcategory items and only included questions that were between subcategory, as these are the strongest test of our hypothesis.

The animals were chosen based on three criteria: (a) they had to plausibly possess psychological states, (b) they had to represent a range of animals to ensure a greater range of biological and psychological processes, and (c) young children should be at least somewhat familiar with them (even if never having a direct encounter). The following were the eight animals we chose: dog, cat, horse, monkey, elephant, camel, fish, and bird.

We once again divided the various biological and psychological processes into two subcategories per domain. The psychological subcategories were the same as in Experiment 1: *cognitive* and *emotional*. The biological subcategories, however, were changed. One subcategory, *anatomy*, focused on an animal's anatomical features and their adaptive value. The second subcategory, *physiology*, consisted of physiological processes such as growth, digestion, breathing, and body temperature regulation. We chose to divide the biological processes into these two subcategories because one concerns static structures and the other concerns dynamic processes, presumably one of the largest possible contrasts within the domain of biology.

There were a total of 24 biological and 24 psychological processes (12 in each subcategory) in Experiment 2. Each animal was associated with 6 processes—3 biological and 3 psychological. This allowed us to present participants with both a biological and psychological question for each animal (the other 4 processes were used as answer options for these two questions). This means that the same animal was mentioned in both the question and its two answer options. For example, if we presented participants with the question, "If I want to know how cats remember their way home (cat–cognitive), who should I ask?" both answer options would also apply to cats: "Someone who knows why cats have blood in their bodies (cat–anatomy), or someone who knows why cats have fun playing with yarn (cat–emotional)?" Keeping the animal consistent between the question and its answer options ensured that participants were choosing their answer based on the similarities and differences between the *processes* presented rather than the animals subject to those processes.

Each participant was given a total of 16 questions: 8 biological and 8 psychological (4 from each subcategory). A complete list of the stimuli can be found in Appendix B with an asterisk next to those processes that were used as questions.

Just as in Experiment 1, latent semantic analysis was used to make sure that neither of the answer options was more strongly associated with the process in question. We also included two counterbalancing conditions as in Experiment 1 (one group of participants would see a pair of answer options with a biology question whereas the other group of participants would see the same pairing with a psychology question) to make sure there was no inherent preference for either of the answer options. As in Experiment 1, we also controlled for other factors children could use as simple heuristics in making their judgments.

Adult participants were once again given the questions in a paper-and-pencil format. The kindergartners were asked the questions by the experimenter, each question accompanied by a pictorial representation of each process for memory purposes.

Procedure. The procedure was identical to that of Experiment 1 for both the children and adults. This included using the same training task and two crucial practice items with the children.

Results

As in Experiment 1, accuracy was computed as the average proportion of questions for which participants correctly matched processes within the two domains. No differences were found between the two different groups that counterbalanced the question and answer pairings for the kindergartners ($M = .75$, $SD = .07$ vs. $M = .73$, $SD = .10$), $t(22) = .53$, $p = .60$, or adults ($M = .82$, $SD = .07$ vs. $M = .87$, $SD = .10$), $t(22) = 1.23$, $p = .23$, so we collapsed the scores within each age group for the remaining analyses. The results from Experiment 2 are depicted in Figure 2.

Once again, adults were used as a baseline to compare the performance of kindergartners. Both adults ($M = .85$, $SD = .09$), $t(23) = 19.33$, $p < .001$), and kindergartners ($M = .74$, $SD = .09$),

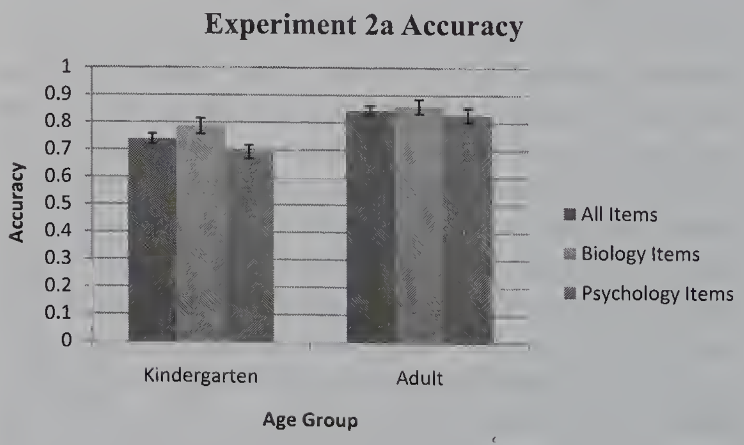

Figure 2. Experiment 2a accuracy scores for both kindergartners and adults. The overall accuracy is represented in the first bar for both age groups. The second two bars represent accuracy for biology and psychology items separately.

$t(23) = 13.65$, $p < .001$, performed significantly above chance on the overall task, although once again adults performed better than the kindergartners, $t(46) = 4.13$, $p < .001$. We also examined performance on the biology and psychology items separately. Adults scored significantly above chance on both the biology ($M = .86$, $SD = .13$), $t(23) = 10.12$, $p < .001$, and the psychology questions ($M = .83$, $SD = .12$), $t(23) = 12.73$, $p < .001$, and performed equally well in both domains, paired-$t(23) = .82$, $p = .42$. Kindergartners scored slightly better on the biology than on the psychology items ($M = .79$, $SD = .14$ and $M = .70$, $SD = .12$, respectively) paired-$t(23) = 2.33$, $p = .03$; however, they performed significantly above chance in both domains—biology, $t(23) = 10.12$, $p < .001$, and psychology, $t(23) = 7.83$, $p < .001$. Furthermore, both kindergarten and adult accuracy reached significance for all four biological and psychological subcategories (anatomy, physiology, emotion, and cognition).

These results demonstrate that kindergartners are capable of distinguishing biological from psychological processes, even when presented with a wide range of living organisms. Furthermore, all of the questions used in Experiment 2a were between subcategory, requiring that participants abstract across the full range of processes within each domain.

Discussion

Experiment 2a replicated the results from Experiment 1a, demonstrating that kindergartners are capable of making very subtle distinctions between biological and psychological processes, distinctions they would only be capable of making if they sensed some underlying coherence uniting all of the biological processes into a single domain.

Experiment 2b

Just as Experiment 1b ensured that participants could not rely solely on the pictures to perform successfully in Experiment 1, we included the same test for the pictures used in Experiment 2.

Method

Participants. Participants were 15 kindergartners (M = 5 years 10 months; 8 males, 7 females) who were recruited from local elementary schools and were predominantly from a White upper-middle-class background. The parents of all children gave written consent and each child agreed to participate. The kindergartners were tested in a quiet room at their school and were compensated with a sticker and a certificate.

Materials and procedure. The same picture triads from Experiment 2a were presented to participants without the verbal descriptions of the processes they represent. These participants were asked which of two pictures "went with" or was "more similar to" the third target picture. A total of 32 picture triads (16 from each counterbalanced group in Experiment 2a) were presented to the participants.

Results

As in Experiment 1b, accuracy was computed as the average proportion of questions for which participants matched pictures depicting processes within the same domain. Once again, the kindergartners performed only at chance when matching pictures in the triads without knowing the processes they represent ($M = .50$, $SD = .07$), $t(13) = .23$, $p = .82$, even when analyzed separately for both counterbalanced groups ($M = .55$, $SD = .12$), $t(13) = 1.65$, $p = .12$, and ($M = .46$, $SD = .13$), $t(13) = 1.26$, $p = .23$, respectively.

These results confirm our hypothesis that the pictures used in Experiment 2a were not driving the kindergartner's successful performance on the task. Rather, it was knowledge of the processes these pictures represent that allowed children to appropriately cluster items into the domains of biology and psychology.

Discussion

Both Experiments 1 and 2 demonstrate that kindergartners appropriately cluster biological processes with one another while separating them from psychological ones. These results suggest that young children sense some deeper similarity among processes in the biological domain. In other words, even kindergartners understand more than the simple idea that illness is caused by contagions or that physical traits are determined by parentage not friendship. These children are capable of looking at a diverse range of biological processes and classifying them together, separate from processes in the domain of psychology.

However, two critical questions remain to be answered before we can conclude that children recognize the fundamentally different nature of biological and psychological phenomena. First, *what* allows children to distinguish among them? Do children have a clear understanding of how they differ or do they simply sense that one biological process is *more* similar to another process within biology than one that is psychological? In other words, is this a principled difference or simply one that is a matter of degree? Second, *what* do children think are the underlying similarities uniting the range of processes within each domain? We have yet to show that kindergartners understand that phenomena within these two domains are *fundamentally* similar—stemming from similar causal mechanisms. Experiments 3 and 4 address this issue.

Experiment 3

Method

Participants. Participants were 16 kindergartners (*M* = 5 years 10 months) and 16 undergraduates with approximately an equal number of males and females in each age group. The scores from 2 additional kindergartners were dropped for failure to complete the experiment. The children were recruited from local elementary schools and were primarily from an upper-middle-class background. The parents of all children gave written consent and each child agreed to participate. The children were tested in a quiet room at their school and were compensated with a sticker and a certificate. The undergraduates were recruited from university sign-up sheets and received minimal compensation (a candy bar) for their participation.

Materials. In Experiment 3, we used many of the same processes from Experiment 1 but presented them to participants in a different context. In the two previous experiments participants were asked to match one of the answer options with the target in question. In this experiment, however, participants were given two processes in the question and asked how *causally* similar they were to a third. Both processes in the question were from the same domain (both biological or both psychological), whereas the third process was either from a different subcategory in that domain or from a different domain altogether. The questions asked in Experiment 3 had the following format: "Something happened to Mary a long time ago. Ever since then, Mary is not as lazy as she used to be (psychological). And ever since then, Mary helps others more than she used to (psychological). How much do you think what happened to Mary also made a difference for how often she gets sore throats (biological)?"

Participants were asked to give a rating on a scale of 1–5 (1 meaning there would be no effect on the third item and 5 meaning there would be a very large effect on the third item). For half of the items, two psychology processes were stated in the question whereas for the other half, the two processes were biological. We used two, rather than one, items in each question to demonstrate that the source of change to one process can result in a change to another. This was intended to demonstrate the salience and plausibility of causal influence. Also, for half of the psychology questions, the target phenomenon to be rated was biological (between domain) whereas in the other half it was psychological (within domain). The biology questions had the same structure. Just as in Experiments 1 and 2, we performed latent semantic analysis on all of the items to make sure the target process was equally related to the processes in question for both the within- and between-domain items. There were a total of 12 questions in this first task.

These questions were designed to tap into children's understanding of the causal mechanisms behind biological and psychological processes. Children should rate the target item as having a high likelihood of being affected if it corresponds to the same domain of processes (biology or psychology) presented in the question and low if it does not. This is because if some change occurs that affects the causal mechanism in a given domain, many processes within that domain (and not other domains) are likely to be affected.

As mentioned in the Introduction, one crucial way to assess whether children are invoking causal reasoning when thinking about biological and psychological processes is to ask them to reason about interventions. To that end, in the second part of Experiment 3, we used a method developed by Lockhart and her colleagues (Lockhart et al., 2002; Lockhart et al., 2008; Lockhart, Aw, et al., 2004; Lockhart, Nakashima, et al., 2004). These researchers conducted the first studies showing how an intervention orientation results in young children clearly distinguishing psychological from biological phenomena. In one set of studies Lockhart, Nakashima, et al. (2004) showed that children as young as 5 years of age saw biological properties (e.g., height and vision) being more influenced by biological interventions than were psychological properties. Similarly, they found that young children saw psychological properties (e.g., being shy or intelligent) as being more influenced by psychological interventions. In addition, they showed that causal reasoning seems to be explicitly elicited in this kind of task format as evidenced by spontaneous comments made by children that invoked causal reasons. This finding on interventions converged strongly with another finding in Lockhart et al. (2004) in which young children attributed the origins of psychological trait differences more to effort and instruction, and the origins of biological trait differences more to inborn factors and a lack of maturation. We used a method similar to that of Lockhart and her colleagues to determine whether the knowledge clustering found in Experiments 1 and 2 was indeed making reference to causal principles.

The second part of this experiment, therefore, explicitly questioned participants about the causal mechanisms underlying the domains of biology and psychology. Participants were given all 12 descriptions from the first part of the experiment (e.g., "Something happened to Mary a long time ago. Ever since then, Mary is not as lazy as she used to be. And ever since then, Mary helps others more than she used to."), but this time participants were asked: "What do you think happened to Mary? Do you think she took a special pill or a special class?" Participants were asked to choose which of the two sources of influence was more likely to apply to the scenario in question. Through questioning participants about the source of influence, we were able to see whether they consistently identify two different types of causation (physical or mental) whenever biological or psychological processes are manipulated.

Procedure. Before beginning the experiment, kindergartners were given a training task to make sure they understood both the questions being asked and the rating scale being used. They were first given a description about how certain changes will or will not influence other things about a particular entity: "So what we're going to do today is talk about things that change. When we make a change to something, sometimes other things also change about it, but not always. For example, if we sharpen a pencil then it will also get shorter and it will also write better. But if we just put a sticker on the pencil, it won't get any shorter or write better. Nothing else changes about the pencil other than the sticker being on it." They were then given two scenarios to practice using the 5-point scale. In one scenario the experimenter asked how likely a change in engine and a change in tires would influence how fast a car could go. In the second scenario the experimenter asked how likely a change in color and a change in seat comfort would influence how fast a car could go. After the participant answered these questions, whether correctly or incorrectly, the experimenter explained why the first scenario would likely make a big difference for the speed of a car while only a small difference or no difference would be seen in the second scenario. These two scenarios helped to demonstrate the causal process behind a change in some entity.

The last practice item given to participants required they not only understand the causal process of change but also be able to infer such a process by its results, given this was the format of the questions in the rest of the experiment. Participants were told that something happened to Carrie a long time ago. "Ever since then Carrie owns a better car than she used to and ever since then Carrie has a nicer house than she used to. How much do you think what happened to Carrie also made a difference for how big of a TV Carrie has?" This question is different from the former scenarios because in this one, owning a nicer house and owning a better car does not *directly* cause Carrie to own a better TV. Therefore participants must infer a third causal mechanism that can influence both of the items given, and then determine whether it would also influence the third target item. The entire training procedure took no more than 5 min, and children's ease with these training questions provides additional support that they understand and reason about underlying causal principles.

Throughout the experiment, participants were randomly asked to repeat the question and answer options and sometimes to explain their answers. No feedback was given to the participants during this time. This questioning was simply to make sure that participants were engaged in the task and were able to remember the question and each answer option.

Adult participants completed this task on paper in a quiet room in our laboratory. They were given written instructions directing them to circle a number on the 5-point scale in the first task and one of the two answer options (special pill or special class) in the second task. The kindergartners were asked the questions by the experimenter, each question being accompanied by a pictorial representation of each process for memory purposes (the same pictures from Experiment 1).

Results

Results from Experiment 3 can be seen in Figures 3 and 4. For the first task in this experiment, the data were analyzed according to whether the item was a within- or between-domain

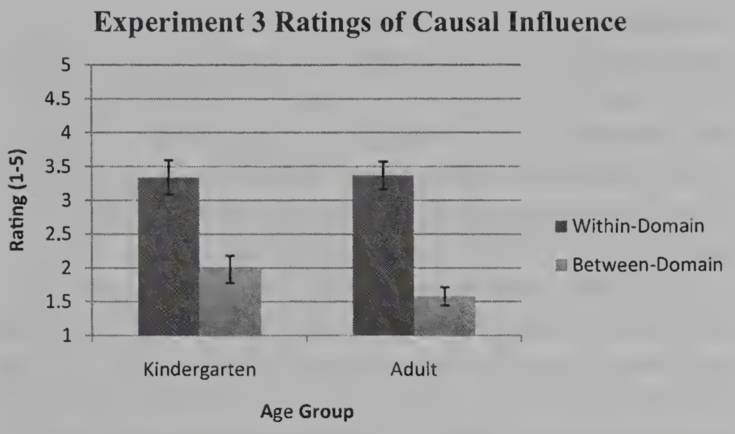

Figure 3. Experiment 3 ratings of causal influence for both within- and between-domain questions. Participants rated on a scale of 1–5 the extent to which changes in processes in one domain affected another process either in the same (within) or in a different (between) domain.

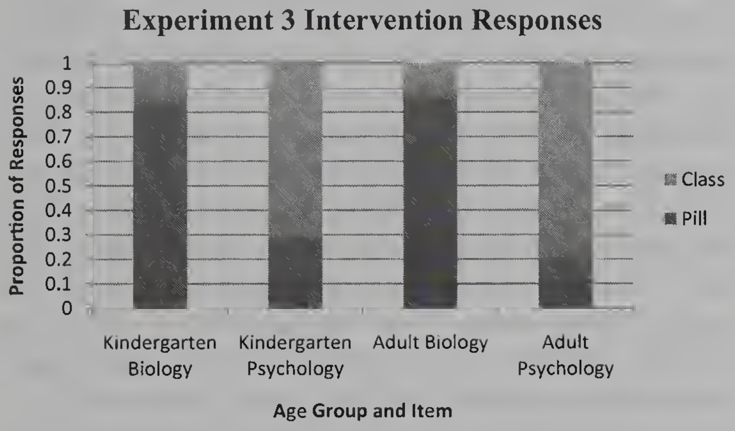

Figure 4. Results for the second part of Experiment 3. Each bar represents the kindergarten and adult responses according to the type of process in question: biological or psychological. Participants chose from two options—taking a "special class" or taking a "special pill"—as the most influential in changing that particular biological or psychological process.

question. The within-domain questions were those in which the target process to be rated was within the same domain as the processes presented in the question. The between-domain questions were those in which the target process to be rated was from a different domain than those previously presented. We expected that the within-domain questions would receive a higher rating on the 5-point scale than the between-domain questions given that if the causal mechanism is affected in one domain, it is likely to affect other processes within, but not outside, that domain.

Our predictions were supported for both adults and kindergartners. Adults gave an average rating of 3.37 out of 5 (SD = .82) for within-domain items and 1.58 (SD = .54) for between-domain items, paired-$t(15) = 9.83$, $p < .001$. Similarly, kindergartners gave higher ratings for the within items (3.34 out of 5, SD = 1.02) than the between items (M = 1.98, SD = .81), paired-$t(15) = 5.59$, $p < .001$. These differences were not driven by higher accuracy for either the biology or psychology questions. Both adults and kindergartners (M = 2.53, SD = .66 and M = 2.42, SD = .55 respectively), $t(15) = 1.49$, p = .16, performed equally well on the items within these two domains (M = 2.67, SD = .83 and M = 2.65, respectively), SD = .75, $t(15) = .29$, p = .78.

The second task required that participants choose the source of change for processes within both the biology and psychology domains. When a participant chose the biological source of change (took a special pill), his or her answer was coded as 0, while choosing the psychological source of change (took a special class) resulted in a score of 1. This allowed us to determine how often participants chose each answer for the biology and psychology items separately. Both adults and kindergartners predominantly chose the biological source of change for the biological processes (M = .146, SD = .120), $t(15) = 11.83$, $p < .001$, and (M = .167, SD = .202), $t(15) = 6.61$, $p < .001$, respectively, and the psychological source of change for the psychological processes (M = .792, SD = .177), $t(15) = 6.58$, $p < .001$, and (M = .708, SD = .177), $t(15) = 4.70$, $p < .001$, respectively.

Results from Experiment 3 reveal that kindergartners grasp the deeper causal mechanisms that structure the domains of biology and psychology. In the first task, we examined the extent to which participants understood that there are deep causal mechanisms affecting all of the processes within, but not outside, a given domain. Ratings of causal influence given by both kindergartners and adults demonstrate the depth of their understanding, giving higher ratings of causal influence to within- than between-domain processes. The second task asked participants to choose between two very different causal interventions (pill vs. class) as the source of change to various biological and psychological processes. Both kindergartners and adults more consistently identified the pill as the source of change for biological processes and the class as having a greater influence on psychological processes.

Discussion

The results from Experiment 3 indicate that even kindergartners have some sense of the fundamentally different causal mechanisms underlying biological and psychological processes, including the kinds of influence these mechanisms can have on such processes.

Just as with Experiment 1, we incorporated a large range of biological and psychological processes but were limited in that the referent was always a human being. We find it unlikely, but possible, that children were using a simpler heuristic on the last task of Experiment 3. It could be that children were basing their answers not on deep intuitions about the causal mechanisms in the biological and psychological domain but rather on social roles associated with the particular processes in question. Children may associate "taking a special pill" with doctors and "taking a special class" with teachers, thereby judging the processes with reference to what a doctor or teacher would know. In other words, children may associate taking pills with "catching colds" and both taking pills and catching colds with "things a doctor would know" without having any knowledge of the causal link between these items (that a doctor understands the causal mechanisms underlying illness in the body). It seems unlikely that children would associate biological processes like "sweating" with doctors or think that only psychological (not biological) processes would fall under the umbrella of knowledge possessed by teachers. However, we decided to directly address this issue in Experiment 4, using a wider range of biological and psychological processes across a wider range of biological referents so as to fully rule out this alternative interpretation of our results.

Experiment 4

Method

Participants. Participants were 16 kindergartners (M = 5 years 10 months) and 16 undergraduates with approximately an equal number of males and females in each age group. The children were recruited from local elementary schools and were predominantly from a White upper-middle-class background. The parents of all children gave written consent and each child agreed to participate. The kindergartners were tested in a quiet room at their school and were compensated with a sticker and a certificate. The undergraduates were recruited from university sign-up sheets and received minimal compensation (a candy bar or Snapple) for their participation.

Materials. The materials used in Experiment 4 were a subset of the animal biological and psychological processes from Experiment 2. We selected 16 processes (2 biological and 2 psychological) from four different animals (cat, bird, horse, and monkey). Four of the possible 6 processes were chosen from four of the possible eight animals. We chose those processes for which a causal intervention would make the most sense. For example, a process such as "Fish first grow in eggs" was not selected as it would be difficult to imagine how that process could be enhanced through any causal intervention, biological or otherwise. A process such as, "A cat grows sharp claws on its paws," however, could conceivably be influenced by some biological intervention—one that could potentially make claws grow quicker or sharper.

Participants were told that some change occurred for each of these processes and were questioned about the source of that change (the change presented always enhanced the process in question). For example, one of the cat biological processes from Experiment 2 was: "Cats grow sharp claws on their paws." In the present task the item was framed in the following way: "Something happened to this cat a long time ago, and ever since then, the cat grows even sharper claws on its paws. What do you think happened to the cat?" For all of the items, participants were presented with a forced choice between two answer options: the animal had an "operation" or the animal had "training." These two answer options mirrored the "pill" and "class" options from Experiment 3. This contrast was for the same purpose: to see whether participants consistently identify two different types of causation (physical or mental) whenever biological or psychological processes are affected. We changed the options from "pill" and "class" to "operation" and "training," however, as the processes now under consideration apply to animals, not human beings. We therefore needed more plausible means of influencing an animal's biology and psychology rather than having birds take pills and having horses sit through classes. We also thought that kindergartners, likely being unfamiliar with operations and even animal training, would not have strong associations between these answer options and either specific social roles or the particular biological and psychological processes presented throughout the experiment. In other words, we doubt that any kindergartner has previously heard of a monkey that underwent an operation to make its tail grow even longer. Having no preestablished associations to base their answers upon, participants must rely on a more abstract understanding of causal principles at the foundation of their biological and psychological knowledge to perform successfully on this task.

Participants were presented with all 16 processes and asked to choose between the two sources of change: operation or training. Adult participants were once again given the questions in a paper-and-pencil format. The kindergartners were asked the questions by the experimenter, each question being accompanied by a pictorial representation of each process (the same pictures from Experiment 2).

Procedure. The procedure used in Experiment 4 was nearly identical to the second task in Experiment 3. Participants were presented with 16 biological and psychological processes that had undergone some change. They were instructed to choose which of two causal mechanisms (operation or training) was the most plausible intervention for each of these items.

Kindergartners, being familiar with both pills and classes, required no explanation of these answer options in Experiment 3. However, the level of knowledge kindergartners have regarding operations and/or training is likely to be very little. To make sure all the kindergartners possessed a sufficient amount of knowledge about these answer options, we introduced them to the task in the following way: "Sometimes things happen and it makes animals different in some way. For example, something could happen to make an animal a faster runner. Or something could happen and it might make the animal nicer to other animals. I am going to tell you about different animals that have changed in some way. I'll tell you how they are different now than they used to be. I want you to tell me what you think happened to the animal to make it different, what you think made it change. There are two things that could have happened to the animal: it could have had an operation, or it could have had training. An operation is when people perform surgery on an animal; they go into the animal and change things deep inside of it. Training is when an animal learns new things from either people or other animals. So, I will tell you about an animal and something that changed about the animal. You will tell me if you think the animal is different because it had an operation, or because it had training. Pick whichever one you think made the animal different now than it used to be." These instructions were intended to give kindergartners enough information about operations and training that they could complete this task as they did previously with the "pill" versus "class" options. However, we left the instructions vague enough that kindergartners were not told explicitly *how* operations or training affected an animal's body or mind. It was up to the individual kindergartners to decide what would most likely affect any given process (e.g., such as getting scared): things changed deep inside the animal or things learned by the animal.

Adults received a shortened version of these instructions and performed the task with paper and pencil in a quiet room in our laboratory. The kindergartners were asked each question by the experimenter, and were tested in a quiet room at their elementary school.

Results

Results for Experiment 4 can be seen in Figure 5. Participants were asked to make a forced choice about the source of change to biological and psychological processes. When a participant chose the biological source of change (had an operation), his or her answer was coded as 0, while choosing the psychological source of change (had training) resulted in a score of 1. This allowed us to determine how often participants chose each answer for the biology and psychology items separately. Both adults and kindergartners predominantly chose the biological source of change for the biological processes ($M = .15$, $SD = .24$), $t(15) = 5.84$, $p < .001$, and ($M = .159$, $SD = .13$), $t(15) = 10.86$, $p < .001$, respectively, and the psychological source of change for the psychological processes ($M = .72$, $SD = .25$), $t(15) = 3.55$, $p < .003$, and ($M = .91$, $SD = .13$), $t(15) = 12.43$, $p < .001$, respectively.

These results demonstrate that even kindergartners understand the fundamentally different causal mechanisms influencing biological and psychological

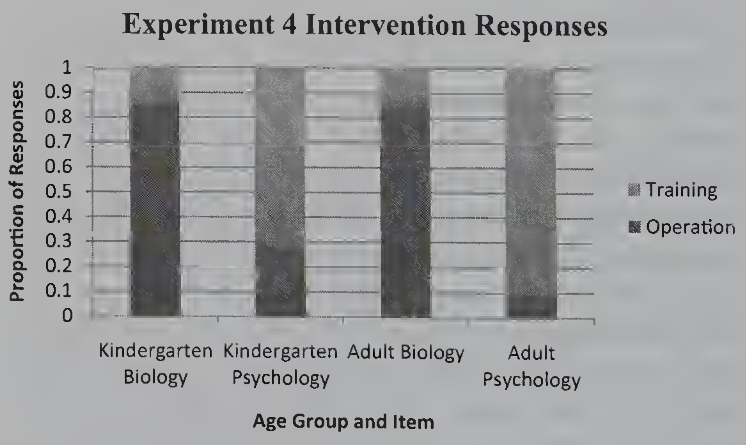

Figure 5. Results for Experiment 4. Each bar represents the kindergarten and adult responses according to the type of process in question: biological or psychological. Participants chose from two options—undergoing an "operation" or "training"—as the most influential on that particular biological or psychological process.

processes, even when taken outside the familiar realm of human biology and psychology and applied across a range of animals.

Discussion

Experiments 3 and 4 went beyond both Experiments 1 and 2, allowing us to gain insight into how children were clustering biological and psychological phenomena. Not only do children understand that these processes are different from one another (as was demonstrated in Experiments 1 and 2), but they understand these processes are *fundamentally* different, that is, based on very different causal mechanisms. Having this understanding of domain-specific causal mechanisms allows children to not only differentiate within- from between-domain processes but also to grasp the fundamental similarity uniting different processes within a given domain. In other words, children not only recognize that biology and psychology are different, but how biological processes are *similar* to one another, as are psychological ones. This understanding provides children with the means to reason successfully about how different processes within a domain are related to one another, how changes in one can lead to changes in another, and how these changes are mediated through specific causal mechanisms.

General Discussion

In addition to having knowledge within the domains of biology and psychology, as was illustrated in the introduction, it appears that children as young as 5 years old also have an understanding that the processes within these two domains are fundamentally similar in that they are subject to the same underlying causal principles. Children know more than simply that some things grow or reproduce, and thus they possess some biological knowledge that is independent of any psychological-explanatory framework. These four experiments suggest that children also understand that processes such as growth and reproduction are phenomena that should be integrated into one domain (biology) united by common causal mechanisms, ones that are different from those operating in the domain of psychology.

We can conclude from Experiments 1 and 2 that young children have strong intuitions about the contrast between the very large domains of psychology and biology. Furthermore, Experiments 3 and 4 demonstrate that children understand this contrast stems from different causal frameworks. What remains to be discovered is *what* children think are the underlying causal mechanisms and *how* they influence various biological processes. Do children have a rich understanding of these causal mechanisms and how they function, or do they only have a skeletal framework that allows them to make limited inferences and inductive generalizations? We have seen a theme emerge in the recent literature that young children often pick up on abstract patterns that differentiate categories before grasping all the concrete mechanisms. For example, Simons and Keil (1995) found that young children understand that living things, nonliving natural kinds, and artifacts have different insides from one another but were unclear about what exact insides are in each. The ability to identify broad domains through sensing abstract causal patterns may be critical to guiding children to look for more mechanistic contrasts as their knowledge develops further. Children may need to have some sense that broad domains of regularities have critically different causal bases before investing the time into trying to master the details of such differences. It may also be that certain kinds of general causal schemata, such as a teleological orientation, increases sensitivity to the biological–psychological contrast by highlighting broad causal-functional patterns that fit differently with two domains although not appealing to specific mechanisms (Opfer & Siegler, 2004).

There is further evidence that learning specific causal mechanisms may vary across cultures. These four studies were performed in the United States, but Lockhart et al. (2004) examined children's beliefs about biological and psychological interventions in both the United States and Japan (see also Lockhart et al., 2008). Although both cultural groups at all ages distinguished biological from psychological properties in terms of which interventions were seen as most important, there was also a cultural difference. Japanese participants were more likely than U.S. participants to select effort as the most effective intervention for changing physical traits whereas U.S. participants chose taking medicine more often than Japanese participants. This cultural difference raises the important question of whether the kinds of expertise clusters found here might be present in many cultures, but might stress different underlying causal influences as most central. Thus, young children may sense a key difference between broad domains but local cultures may guide them toward weighing different kinds of causal patterns as most essential.

Another remaining question concerns how young children come to understand the fundamental differences between these two domains in the first place. The particular tasks used in these studies were verbally laden and thus were not successful in pilot studies with preschoolers. However, future studies might reduce the verbal loads of such tasks to discover how children begin to make the distinction between processes in the biological and psychological domains. There is now considerable controversy about the idea that knowledge of biology stems from a previous understanding of psychology (Waxman et al., 2007). Studies with younger children may help determine the origins of this biological understanding, especially how children learn the causal mechanisms foundational for all biological processes and how these relate to the contrast between the psychological and biological world.

The extent to which early educational intervention, early cumulative risk, and the early home environment were associated with young adult outcomes was investigated in a sample of 139 young adults (age 21) from high-risk families enrolled in randomized trials of early intervention. Positive effects of treatment were found for education attainment, attending college, and skilled employment; negative effects of risk were found for education attainment, graduating high school, being employed, and avoiding teen parenthood. The home mediated the effects of risk for graduating high school, but not being employed for teen parenthood. Evidence for moderated mediation was found for educational attainment; the home mediated the association between risk and educational attainment for the control group, but not the treated group.

Numerous studies have documented the negative impact of multiple social risk factors on children's development from early childhood through adolescence (e.g., Sameroff, Seifer, Barocas, Zax, & Greenspan, 1987; Trentacosta et al., 2008). High-quality early educational programs are widely viewed by researchers, parents, and policy makers as a means of enhancing cognitive and social skills for young children exposed to such risk factors (Heckman, 2006). Enhancing early development is expected to lead to more positive educational, occupational, and social outcomes in adulthood. Findings from the Abecedarian Project, a study of intensive early educational intervention delivered to high-risk children in a child-care setting, support this expectation by demonstrating that individuals randomly assigned to early educational treatment, when compared with those assigned to the control group, maintained cognitive gains and showed educational and occupational benefits into young adulthood (Campbell, Pungello, Miller-Johnson, Burchinal, & Ramey, 2001; Campbell, Ramey, Pungello, Sparling, & Miller-Johnson, 2002). Long-term educational and occupational benefits were replicated in a subsequent randomized study of early education, the Carolina Approach to Responsive Education (CARE; Campbell et al., 2008). The present study adds to the literature concerning the long-term effects of educational intervention and early risk by examining: (a) the extent to which exposure to multiple social risk factors in early childhood predicts outcomes in young adulthood over and above the effects of early educational intervention within a high-risk sample, and whether early risk and early intervention interact to influence adult outcomes, and (b) whether such distal risk factors are

associated with adult outcomes through proximal processes associated with the quality of the early home environment, and whether early intervention moderates the effects of the proximal processes in the early home on young adult outcomes.

Early Educational Intervention and Early Cumulative Risk

Head Start, public prekindergarten, and, to a lesser extent, subsidized child-care programs have been funded by local, state, and federal governments in an effort to enhance the early development of children raised in poverty to help them overcome their increased risk of academic failure, unemployment, teenage parenthood, and criminal behavior as young adults. These efforts have been undergirded by results from randomized experiments demonstrating enhanced outcomes associated with high-quality preschools or educational intervention in child-care settings targeting poor children (Berrueta-Clement, Schweinhart, Barnett, Epstein, & Weikart, 1984; Campbell et al., 2001, 2008; Hubbs-Tait et al., 2002) and observational studies suggesting that quality child care enhances children's development (see Vandell, 2004, for a review). Both the Abecedarian and CARE studies found positive effects for young adult education and occupational outcomes (Campbell et al., 2002; Campbell et al., 2008). More specifically, compared to controls, those who received the early educational intervention attained more years of education, were more likely to attend a 4-year college or university, and were more likely to have obtained skilled employment. However, no significant differences were found in either sample for high school graduation or employment rates. In addition, those treated in the Abecedarian Project were less likely to be teen parents compared to controls, although this was not replicated in the CARE sample. Neither the Abecedarian nor CARE projects found reductions in criminal behavior, but such effects were found for the Perry Preschool Study (Schweinhart, Barnes, & Weikart, 1993).

The multiple-risk model proposed by Rutter (1979) and Garmezy, Masten, and Tellegen (1984) posits that developmental outcomes are a function of individual responses to risk factors. This model focuses on pathways to competence in the context of adversity (Masten et al., 1999) and emphasizes identifying "protective factors" that weaken the link between adversity and child outcomes and promote "successful adaptation despite challenging or threatening circumstances" (Masten, Best, & Garmezy, 1990, p. 426). The multiple-risk approach focuses on risk composites that describe the extent of exposure to various factors based on the recognition that distal indices such as poverty, single parenthood, large households, low parental education, unemployment, low-income communities and poor-quality schools, and more proximal measures, such as maternal depression and lack of social support, tend to cluster in the same individual (Masten et al., 1995). Accounting for these correlated constraints through multiple or cumulative risk indices may provide better theoretical and empirical models of how exposure to negative factors impacts children's development than does examining any single individual risk factor or examining them in an additive manner (Sameroff & MacKenzie, 2003).

Several studies have demonstrated that high scores on multiple risk indices are negatively related to cognitive, language, and socioemotional outcomes in early childhood, middle childhood, and adolescence (Brody & Flor, 1998; Brody, Kim, & Murry, 2003; Burchinal, Roberts, Hooper, & Zeisel, 2000; Burchinal, Roberts, Zeisel, Hennon, & Hooper, 2006; Evans, 2003; Forehand, Biggar, & Kochick, 1998; Gerard & Buehler, 2004; Gutman, Sameroff, & Eccles, 2002; Gutman, Sameroff, & Cole, 2003; Hooper, Burchinal, Roberts, Zeisel, & Neebe, 1998; Jones, Forehand, Brody, & Armistead, 2002; Krishnakumar & Black, 2002; Liaw & Brooks-Gunn, 1994; Linver, Brooks-Gunn, & Kohen, 2002; Luster & McAdoo, 1994; Prelow & Loukas, 2003; Pungello, Kupersmidt, Burchinal, & Patterson, 1996; Sameroff, Seifer, Baldwin, & Baldwin, 1993; Sameroff et al., 1987; Trentacosta et al., 2008). Less is known, however, about the very long term effects of early exposure to multiple risk factors. Young adulthood, spanning ages 18–25, is a time termed "emerging adulthood" by Arnett (2000), a life stage encompassing the transition between separation from the family of origin and becoming self-supporting. Previous research has linked individual early risk factors to young adult education outcomes, employment, teen parenthood, and criminal behavior (Aquilino, 1996; Ensiminger & Slusarcick, 1992; Gest, Mahoney, & Cairns, 1999; Haurin, 1992; Jaffee, 2002; Jimerson, Egeland, Sroufe, & Carlson, 2000; Xie, Cairns, & Cairns, 2001; Zill, Morrison, & Coiro, 1993), but to date, less research has examined whether exposure to multiple social risk factors during early childhood predicts adult outcomes. An exception is a study of over 30,000 individuals in Britain in which Schoon et al. (2002) found increased socioeconomic risk to be associated with lower academic attainment through adolescence and lower social class attainment in adulthood.

Studies examining the effects of cumulative risk often include income and ethnicity among the multiple risk indices, yet investigating how cumulative risk affects outcomes within samples limited to such individuals is needed given their increased likelihood of experiencing multiple stressors. Children in poverty are more likely to experience both social risk (e.g., family disruption) and environmental risk (e.g., pollution; see review by Evans, 2004). African American children often experience racism in addition (Luster & McAdoo, 1994). Thus, ''sociocultural forces such as poverty and racism tend to allocate risk disproportionately… to subsets of the population such as poor and ethnic minorities'' (Evans, 2003, p. 924). Using heterogeneous samples, researchers have investigated the effects of additional risk over and above those associated with income and ethnicity, finding somewhat inconsistent results depending on the additional risk included (e.g., stressful life events, Pungello et al., 1996; low birth weight, Liaw & Brooks-Gunn, 1994). Others have examined the effects of additional risk within high-risk samples (Burchinal, Roberts, et al., 2000; Hooper et al., 1998; Shaw, Winslow, Owens, & Hood, 1998; Burchinal et al., 2006; Krishnakumar & Black, 2002; Brody et al., 2003; Gutman et al., 2002; Prelow & Loukas, 2003), finding negative associations between such risk and children's outcomes. However, although some longitudinal work has been carried out (Brody et al., 2003; Burchinal, Roberts, et al., 2000; Burchinal et al., 2006), most of these studies have investigated short-term links between risk and outcomes.

In addition to investigating the main effects of early education in a child-care setting and early cumulative risk, researchers have tested for interactions between early care experiences and early risk. Both compensatory effects (i.e., children with higher risk benefited more than children with lower risk) and leveraging effects (i.e., greater effects found for children with less risk than for those with more risk) have been found. Hubbs-Tait et al. (2002) found children with high family risk benefited more by Head Start attendance than those at low risk when predicting language scores. In contrast, Liaw and Brooks-Gunn (1994) examining the effects of the Infant Health and Development Program found that for children raised in poverty, the intervention had a greater effect for children with less risk than for children who experienced more risk.

The first goal of this study was to further the understanding of the effects of early intervention and early cumulative risk by: (a) investigating the associations between exposure to multiple social risk factors in early childhood and young adult outcomes within a sample drawn entirely from low-income families, almost all of whom were African American, over and above the effects of early educational intervention, and (b) examining whether early intervention and early risk interact to influence outcomes in young adulthood.

Moderated Mediation: The Early Home Environment

A number of risk indices have been constructed to examine how exposure to risk negatively affects developmental outcomes. Although both distal (e.g., poverty, unsafe neighborhoods, maternal education) and proximal (e.g., quality of the home environment) factors have often been included in risk indices (Barocas et al., 1991; Hooper et al., 1998; Luster & McAdoo, 1994; Prelow & Loukas, 2003; Sameroff et al., 1993), more recent studies have focused on how exposure to distal risk factors affects development via proximal processes (e.g., Brody et al., 2003; Trentacosta et al., 2008). Based upon ecological theory (Bronfenbrenner & Morris, 1998), researchers have hypothesized that the stress and lack of opportunities associated with poverty, low education, and large households may significantly diminish the family's psychological strengths, resulting in less responsive care by parents (e.g., Conger & Elder, 1994). Thus, not only do risk factors tend to cluster together, but the co-occurrence of multiple risks may overwhelm the family's ability to cope and provide positive parenting to the child (Sameroff et al., 1987).

A number of explanatory models have been tested in previous work, including additive (testing for independent effects of each variable), cumulative (testing the effect of a total risk score), interactive (testing if proximal variables moderate the effects of distal variables), and mediational (testing if the effects of distal variables are mediated through their effects on proximal variables), with the mediation model receiving the greatest support (e.g., Jones et al., 2002; Krishnakumar & Black, 2002). For example, proximal factors such as the quality of the home environment mediated distal risk factors in predicting cognitive outcomes prior to the age of 6 years (Barocas et al., 1991; Krishnakumar & Black, 2002), externalizing and internalizing problems among high-risk children in early childhood (Trentacosta et al., 2008), academic and social outcomes among

African American children in Grades 1–3 (Burchinal et al., 2006), and social outcomes for African American children 7–15 years of age (Brody et al., 2003; Jones et al., 2002). Thus, the weight of evidence from these and other prior studies supports the hypothesis that distal risk factors, such as poverty, maternal education, and family structure, predict child outcomes through effects on proximal processes (Guo & Harris, 2000; Guo & VanWey, 1999; Luster & McAdoo, 1994; National Institute of Child Health and Human Development Early Child Care Research Network, 2005). However, less is known about the duration of these effects, that is, the extent to which risk early in the life span may influence the quality of the home environment in early childhood, which may in turn affect outcomes across many years, even into young adulthood.

In addition, researchers have examined whether early care experiences may moderate the effects of the early home environment, finding both compensatory (Bradley, Corwyn, Burchinal, McAdoo, & Garcia-Coll, 2001) and leveraging (Bryant, Burchinal, Lau, & Sparling, 1994) effects. This is similar to findings from the studies examining the interaction between early care experiences and early cumulative risk described earlier.

The second overall goal of this study was to further understanding of the role of the early home environment by: (a) examining whether the early home environment mediates the effects of early cumulative risk on young adult outcomes and (b) investigating whether early educational intervention in a full-time child-care setting moderates the effects of the early home environment on young adult outcomes.

Present Study

This study used data from the Abecedarian Project (Ramey & Campbell, 1984) and CARE (Wasik, Ramey, Bryant, & Sparling, 1990) to examine the very long term effects of early educational intervention in a child-care setting, early multiple risk exposure, and the early home environment. These consecutive longitudinal programs have followed participating individuals from infancy through young adulthood. Early risk factors and the home environment were assessed during program implementation from infancy through age 5 (kindergarten entry), and the data on early circumstances were entered into predictive models to explain educational outcomes, employment outcomes, teen parenthood, and criminal behavior when these persons were 21–25 years of age.

Our hypotheses were as follows. Concerning the first overall goal of the study, prior analyses with these samples have demonstrated that those who received the early educational intervention showed benefits in terms of education and vocational outcomes (Campbell et al., 2002; Campbell et al., 2008). We hypothesized that within this high-risk sample, over and above any found effects of treatment, early cumulative risk would be negatively associated with young adult educational outcomes (education attainment in general, graduating high school specifically, and attending college specifically), employment outcomes (being employed, obtaining skilled employment), avoidance of teen parenthood, and avoidance of criminal behavior (i.e., individuals exposed to more risk would be more likely to be convicted of a misdemeanor, more likely to be convicted of a felony, and more likely to use illegal drugs). We also hypothesized that early intervention would moderate the effects of risk such that the effects of increased risk would be weaker for those who received the intervention than for those who did not. Concerning the second goal of the study, we hypothesized that the early home environment would mediate any found effects for early risk and that early educational intervention would moderate the effects of the early home environment such that the effects of a poor-quality home environment would be weaker for those who received treatment compared to those who did not.

Method

Participants

Participants were 139 young adults enrolled as infants in one of the two consecutive trials of early educational intervention. The Abecedarian study enrolled four cohorts of infants born between 1972 and 1977, and CARE added two more born between 1978 and 1980. To determine eligibility for both samples, families were screened with the same High Risk Index (Ramey & Smith, 1977) composed of sociodemographic factors associated with delays in cognitive development and educational failure. Among the factors were the educational levels of parents, family income, family structure, evidence of cognitive delays or academic failure in other family members, and the use of welfare funds to meet basic needs. Scores on the index were weighted and summed to measure the degree of risk for each family; to qualify, a score of 11 or higher was required.

The original Abecedarian sample consisted of 111 infants; CARE consisted of 66. Ninety-four percent of the original high-risk families in the combined sample identified themselves as African American (the remaining 6% were Euro-American), and 53% of the infants were male. In the Abecedarian study, infants were randomly assigned to two groups: full-time educational treatment in a child-care setting or control. In the CARE study, infants were randomly assigned to three groups: full-time educational treatment in a child-care setting plus family education, family education only, or control. Table 1 summarizes for both samples the numbers of male and female study participants for whom data were collected in young adulthood. Attrition across the two studies was only 6%. At the time of the young adult follow-up, the individuals ranged in age from 20 to 25 years. For the Abecedarian study, the mean age at data collection was 21.2 years (*SD* = 0.60 years); for CARE, the mean age was 22.5 years (*SD* = 0.71 years).

Given that one of the main interests in this study was to learn the degree to which the early childhood educational treatment in a child-care setting influenced later outcomes in light of early risk and the quality of the early home environment, the present analyses were confined to individuals who received early educational treatment within the child-care setting (whether or not they also received family education) and those randomly assigned to the control groups. Thus, the treated group consisted of the Abecedarian treated group (*n* = 53), and the CARE treated group (*n* = 14). The control group consisted of the Abecedarian control group (*n* = 51), and the CARE control group (*n* = 21). The CARE group that received only the family education (*n* = 25 families) was not included in these analyses (see Wasik et al., 1990, for comparisons of early childhood outcomes for three CARE groups). Thus, the total sample size for the present analyses was 139 (73 males and 66 females; 67 who received early educational treatment and 72 controls). Analyses of young adult outcomes for the Abecedarian and CARE projects have been based on an "intent-to-treat" model in which all individuals were classified according to their random group assignment in infancy. For specific outcomes, the numbers vary slightly depending upon the few young adults who chose not to disclose certain information.

Table 1
Number of Abecedarian and CARE Study Participants Interviewed as Young Adults

	Abecedarian		CARE		
Group	Males	Females	Males	Females	Total
Early educational treatment	28	25	9	5	67
Control	23	28	13	8	72
Family education only			15	10	25
Total	51	53	37	23	164

Note. The child-care treatment group in the Carolina Approach to Responsive Education (CARE) study received family education as well.

Although the Abecedarian and CARE studies comprised separate samples, several factors provide confidence that they can be combined into one sample. First, the children in both the Abecedarian and CARE samples were recruited in the same manner from the same communities, and the center-based treatment in both samples was essentially the same (the early educational intervention staff was relatively stable, they were supervised by the same investigators, and the site and the curriculum were the same). Further, earlier analyses examining the effects of treatment on cognitive outcomes through age 8 found treatment and not sample to be substantively related to outcomes (with IQ differences between the samples being found at only 2 of the 10 assessment points) and no Treatment × Sample interaction (Burchinal, Campbell, Bryant, Wasik, & Ramey, 1997). Prior analyses for age 21 outcomes compared 12 basic background factors (maternal age, education, marital status, teen parent, ethnicity, etc.) across the two study samples and found only one significant difference: Mothers of infants enrolled in CARE had more years of education at the time of the target child's birth (Campbell et al., 2008). These prior young adult analyses also compared the effects of treatment in the samples and found no evidence for a larger treatment effect in the CARE sample (i.e., for individuals who received both the child-care treatment and the family education component) than the Abecedarian sample (i.e., those who received only the child-care treatment) for long-term educational outcomes (Campbell et al., 2008). Finally, in analyses for the current study (described in the following), logistic regression on each of the individual risk factors that comprised the cumulative risk index employed in this study and a general linear model for the risk total score found no evidence that individual risk items or the total scores differed across samples.

Procedures

Treatment and control groups. The Abecedarian and CARE treatment involved early educational intervention beginning in infancy and lasting until the child started kindergarten. Age at entry ranged from 3 to 22 weeks, with a mean age of 9 weeks ($SD = 4.6$ weeks). The intervention was delivered in a full-time child-care facility housed in a university-based research center. Descriptions of the educational program and early childhood outcomes are provided in a number of earlier publications (i.e., McGinness & Ramey, 1981; Sparling, 1989; Sparling & Lewis, 1978, 1984; Ramey & Campbell, 1984; Wasik et al., 1990).

Longitudinal data collection. From infancy to age 5 years (i.e., early childhood), demographic circumstances for each child's family were repeatedly assessed. Data were collected at the point of study admission and at least annually thereafter to track changes in the child's family composition, parental education levels, and stability of living circumstances. Annual home visits were also made during which the educational atmosphere of the child's home environment was assessed. The focus of the present work is on how events in the first 5 years of life were related to long-term outcomes as represented in accomplishments assessed in the young adulthood follow-up.

Young adult follow-up. Young adults were contacted by letter and invited to enroll in this phase of the study. Assessors were advanced graduate students in clinical or school psychology. All were unaware of the participants' early treatment histories. Two of the assessors were African American and one was European American for the Abecedarian follow-up; the three assessors were European American for the CARE follow-up.

Measures

Early risk. The following variables were selected from data collected between infancy and 54 months to create the present cumulative risk index: teen mother when the participant was born (mother younger than 18), mother's educational level at birth less than high school graduate, parents not married at some point during this time period, participant did not live with the mother at some point during this period, large family size (participant had two or more siblings by age 54 months), and high mobility (the family made three or more moves during this time period). These factors were selected based upon prior studies examining the effects of early risk factors (Aquilino, 1996; Burchinal, Roberts, et al., 2000; Chase-Lansdale, Gordon, Brooks-Gunn, & Klebanov, 1997; Deater-Decker, Dodge, Bates, & Pettit, 1998; Dubow & Luster, 1990; Ensiminger & Slusarcick, 1992; Furstenberg, Brooks-Gunn, & Chase-Lansdale, 1989; Gutman et al., 2002; Hooper et al., 1998; Luster & McAdoo, 1994; McLanahan, 1997; Murry, Bynum, Brody, Willert, & Stephens, 2001; Prelow & Loukas, 2003; Sameroff et al., 1993; Sugawara, 1991; Williams, Anderson, McGee, & Silva, 1990; Zill et al., 1993). The cumulative risk score was derived by summing up 1 point for each of the factors that pertained to the family during the child's first 5 years. Thus, early risk scores could range from 0 to 6.

The early home environment. Abecedarian and CARE families were visited at home when study children were 6, 18, 30, 42, and 54 months of age. Based on observations and questions during the visits, the age-appropriate version of the Home Observation for Measurement of the Environment (HOME; Bradley & Caldwell, 1979; Caldwell & Bradley, 1984) was scored. Versions of the HOME suitable for infants/toddlers and preschool children aged 3–6 covered factors such as the affective quality of the parent (mother)–child interaction, the toys and educational materials provided, the parent's support for the child's learning, the stability of the family's routines, and the variety and breadth of stimulation made available to the child. Caldwell and Bradley (1984) reported internal consistency reliability of $r = .89$ for the infant/toddler version of the HOME, and $r = .93$ for the preschool version (Bradley, Caldwell, Rock, Hamrick, & Harris, 1988). Bradley (1992) found comparable factor structures and predictive validity for European American and African American samples. In the present sample, alpha levels for the HOME ranged from .75 at 6 months to .89 at 54 months, with an overall average alpha of .82.

The infant/toddler and preschool versions of the HOME differ in the number of items but are highly correlated ($.43 < r < .72$). Accordingly, an across-time composite HOME score was computed as the mean of the percent of items passed at 6, 18, 30, 42, and 54 months. This composite HOME score ranged from 0.40 to 0.94 ($M = 0.69$ and $SD = 0.11$). Thus, on average, 69% of the items were passed over time across the families in the sample.

Young adult outcomes. Outcomes for the analyses presented here include educational attainment, employment, teen parenthood, and criminal behavior. These data were collected through means of a semistructured interview covering these and other basic demographic factors. The use of illegal drugs was measured by self-scored answers to questions contained in the Behavioral Risk Factor Surveillance System (Kolbe, 1990).

Educational attainment was operationalized in three ways. First, a continuous measure of education was created based on the number of years associated with the final degree obtained. The score was the highest grade completed if the participant did not graduate from high school or obtain a general equivalency diploma (GED), the score was 12 if the participant had graduated from high school or obtained a GED, 14 if the participant had completed some college or obtained an associate's degree, and 16 if the participant had obtained a bachelor's degree. To address policy questions, two categorical variables were also created: high school graduate (*yes–no*) and ever attended a 4-year college or university (*yes–no*).

Two binary employment outcomes were examined. First, whether or not the participant was employed in any capacity at the time of the young adult interview was analyzed. Second, positions were coded according to the Hollingshead Index of Social Class (Hollingshead, n.d.) and whether or not the participant was employed in a skilled labor occupation or higher (defined as Hollingshead rating of 4 or higher) was coded.

Teen parenthood was defined as having a first child before age 18. Criminal behavior was self-reported: whether or not the participant had been convicted of a misdemeanor, convicted of a felony, or reported any illegal drug use.

Analysis Strategy

Two sets of analyses were conducted to address the two goals of the study. First, the simultaneous effects of treatment and risk were investigated using general linear modeling (in the models predicting to the continuous variable for education attainment) and logistic regression techniques (in the models predicting to the dichotomous outcomes: high school graduate, ever attended college, currently employed, currently employed in a skilled job, teen parenthood, ever convicted of a misdemeanor, ever convicted of a felony, and use of illegal drugs) in SAS version 9.1 (Statistical Analysis Software, Cary, NC). For each outcome, two predictive models were run. The first tested for the main effects of early intervention and early risk; the second added an intervention by risk interaction term to the model.

In the second set of analyses, young adult developmental status was conceptualized within a moderated mediation framework, hypothesizing that the early home environment mediated the effect of early risk on young adult outcomes and that early educational intervention status moderated the relation between the home environment and young adult outcomes (see Figure 1). Thus, for each outcome where significant effects of early risk above and beyond treatment were found in the first set of analyses, the moderated mediation hypothesis was investigated using Mplus version 5 (Muthén & Muthén, 1998–2007). Mplus provides several advantages for this analysis in that it: (a) allows for the proper specification and analysis of binary and continuous outcomes, (b) estimates bootstrapped standard errors and confidence intervals for each model coefficient, and (c) addresses missing data through a full information maximum likelihood (FIML) technique. Following recommendations by Preacher, Rucker, and Hayes (2007), the moderated mediation path model included the early risk index, early home environment, early childhood educational treatment status, and a Home Environment × Treatment interaction term as predictors of young adult outcomes (see Figure 2). Additionally, the home environment was regressed on the child risk index. Each predictor was mean-centered for analysis and for the creation of the interaction term. The analysis plan focused on assessing the significance of simultaneous mediation and moderation within the path models. Significant mediation was determined by a nonzero product term of the a_1 and b_1 paths, controlling for all other variables in the model; this product term is referred to as the indirect effect or mediated effect (MacKinnon, 2008). The term indirect effect is used from this point forward. If the path between the interaction term and outcome was significant for a specific young adult outcome, post hoc evaluation of simple indirect effects within treatment levels was conducted (Tein, Sandler, MacKinnon, & Wolchik, 2004).

Results

Descriptive Findings

The number of early risk factors experienced by study participants ranged from 0 to 4 ($M = 2.31$, $SD = 1.10$). The mean cumulative risk scores were

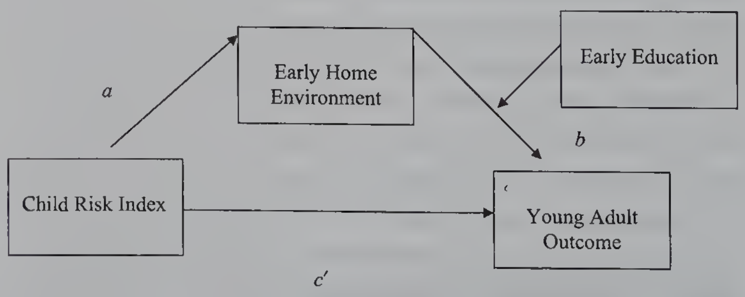

Figure 1. Conceptualization of moderated mediation.

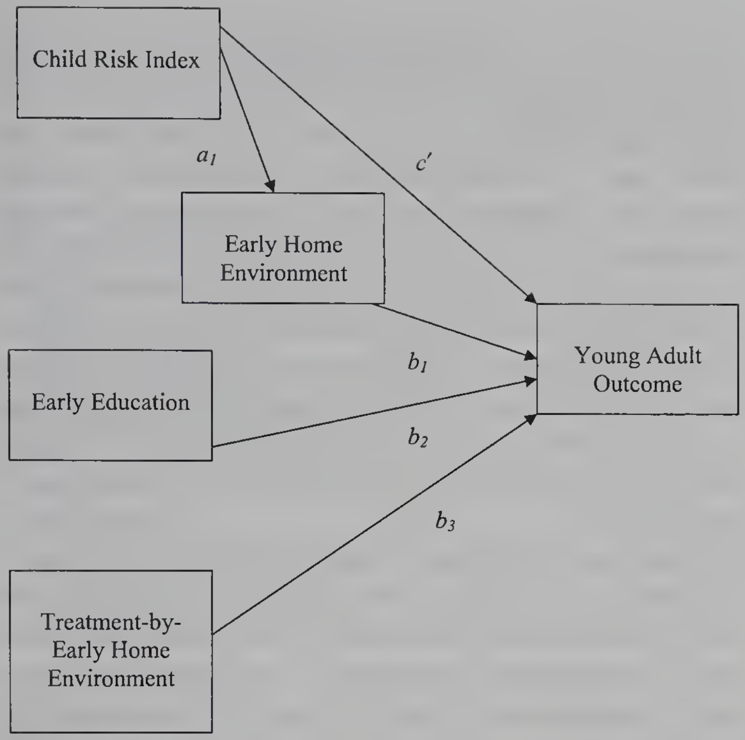

Figure 2. Moderated mediation path model specification.

2.32 ($SD = 1.06$) for the treated group and 2.38 ($SD = 1.18$) for the control group. The mean early home environment score for the treated group was 0.68 ($SD = 0.091$) and for the control group was 0.66 ($SD = 0.10$). There were no significant differences between the treated and control groups for any risk item, the total risk score, or the home environment score.

Table 2 provides the percentages of the treatment and control groups who experienced each risk factor and each of the binary young adult outcomes. Logistic regressions for each of the binary outcomes with only treatment as the predictor found significant differences between the treated and control groups for having attended college, $B = 1.31$ (0.43), $p < .01$, and skilled employment, $B = 0.98$ (0.37), $p < .01$. For the continuous educational outcome, the mean for the total sample was 12.31 ($SD = 1.64$), with $M = 12.77$ ($SD = 1.45$) for the treated group and $M = 11.88$ ($SD = 1.69$) for the control group; a general linear model with treatment alone as a predictor found a significant difference between the treated and control groups for this outcome, $B = 0.90$ (0.27), $p < .01$. The correlation between educational attainment and cumulative risk was $r = -.20$ ($p < .05$), and the correlation between educational level and the early home environment was $r = .36$ ($p < .0001$).

Research Goal 1: Prediction Models

Table 3 presents raw regression coefficients and standard errors for the linear education attainment outcome and odds ratios (ORs) and confidence intervals (CIs) for dichotomous outcomes. The findings indicate that when the effects of treatment and

Table 2

Descriptive Statistics for Individual Risk Factors and Binary Outcomes by Treatment Group

	Group					
	Treated		Control		Total	
	n	% of group	*n*	% of group	*N*	% of sample
Risk factors						
Teen mother	15	22.7	21	29.2	36	26.1
Mother less than high school graduate	37	56.1	46	63.9	83	60.1
Mother not always married	59	89.4	61	84.7	120	87.0
Mother out of home	10	15.5	8	11.1	18	13.0
Large family size	13	19.7	17	23.6	30	21.7
Frequent moves	20	30.3	18	25.0	38	27.5
Outcomes						
High school graduate	50	74.6	48	72.2	98	71.0
Attended college	25	37.9	10	14.8	35	25.6
Employed as young adult	45	67.2	40	56.3	85	61.6
Skilled employment	30	46.2	17	24.3	47	34.8
Teen parent	8	11.9	15	20.8	23	16.6
Misdemeanor	8	12.3	14	19.4	22	16.1
Felony	6	9.2	8	11.1	14	10.2
Used illegal drugs	44	67.7	50	69.4	94	68.6

risk on young adult outcomes were simultaneously estimated, positive treatment effects were found for educational attainment, the likelihood of attending college, and the likelihood of having obtained skilled employment. Risk was negatively associated with educational attainment, the likelihood of high school graduation, the likelihood of being employed in any capacity, and the likelihood of avoiding teen parenthood. Effect sizes indicate that, controlling for risk, treated participants obtained 0.87 more years of education, were 3.82 times more likely to have attended some college, and were 2.69 times more likely to have obtained skilled employment compared to control participants. Controlling for treatment, each additional risk factor was associated with 0.28 fewer years of education, being 1.45 times less likely to graduate from high school, 1.61 times less likely to be employed, and 1.78 times more likely to be a teen parent (for ORs less than one reported in the table, the inverse of the reported value is used to describe the odds). Neither treatment nor risk appeared to have a significant effect on self-reported involvement in crime.

In the second set of models that tested for a treatment by risk interaction in addition to simultaneously estimating the main effects of treatment and risk, no evidence was found to suggest treatment moderated the associations between risk and any of the young adult outcomes.

Table 3

Young Adult Outcomes as a Function of Early Educational Intervention and Early Cumulative Risk

	Model 1			
	Treat		Risk	
	B	*SE*	*B*	*SE*
Education attainment	0.87**	0.27	−0.28*	0.12
	OR	CI	OR	CI
High school graduate	1.30	0.61, 2.77	0.69*	0.49, 0.97
Employed	1.53	0.75, 3.13	0.62**	0.44, 0.87
Teen parent	0.53	0.20, 1.38	1.78*	1.13, 2.80
Any college	3.82**	1.66, 8.80	0.91	0.63, 1.31
Skilled employment	2.69**	1.29, 5.60	0.88	0.63, 1.22
Felony	0.86	0.28, 2.65	1.60	0.94, 2.75
Misdemeanor	0.60	0.23, 1.56	1.51	0.98, 2.33
Illegal drugs	0.90	0.44, 1.85	0.95	0.69, 1.31

Note. Values for treatment and risk were centered for analysis.
$^{*}p < .05$. $^{**}p < .01$.

Research Goal 2: Moderated Mediation

The moderated mediation hypotheses was then tested for each outcome where a main effect for risk was found in the prediction models described earlier (i.e., educational attainment, graduated high school, being employed, and teen parenthood). Table 4 (for the educational outcomes) and Table 5 (for employment) provide the path coefficients, bias-corrected standard errors, and 95% CIs for the model path. In the final row of each table are the coefficient for the indirect effect, along with its bias-corrected standard error and CI.
